Part I
Chapter 1

The base package

---

**base-package**  
*The R Base Package*

**Description**

Base R functions

**Details**

This package contains the basic functions which let R function as a language: arithmetic, input/output, basic programming support, etc. Its contents are available through inheritance from any environment. For a complete list of functions, use `library(help = "base")`.

---

**.bincode**  
*Bin a Numeric Vector*

**Description**

Bin a numeric vector and return integer codes for the binning.

**Usage**

`.bincode(x, breaks, right = TRUE, include.lowest = FALSE)`

**Arguments**

- `x`  
a numeric vector which is to be converted to integer codes by binning.
- `breaks`  
a numeric vector of two or more cut points, sorted in increasing order.
- `right`  
logical, indicating if the intervals should be closed on the right (and open on the left) or vice versa.
- `include.lowest`  
logical, indicating if an 'x[i]' equal to the lowest (or highest, for `right = FALSE`) 'breaks' value should be included in the first (or last) bin.
Details

This is a ‘barebones’ version of cut.default(labels = FALSE) intended for use in other functions which have checked the arguments passed. (Note the different order of the arguments they have in common.)

Unlike cut, the breaks do not need to be unique. An input can only fall into a zero-length interval if it is closed at both ends, so only if include.lowest = TRUE and it is the first (or last for right = FALSE) interval.

Value

An integer vector of the same length as x indicating which bin each element falls into (the leftmost bin being bin 1). NaN and NA elements of x are mapped to NA codes, as are values outside range of breaks.

See Also

cut, tabulate

Examples

## An example with non-unique breaks:
```r
x <- c(0, 0.01, 0.5, 0.99, 1)
b <- c(0, 0, 1, 1)
.bincode(x, b, TRUE)
.bincode(x, b, FALSE)
.bincode(x, b, TRUE, TRUE)
.bincode(x, b, FALSE, TRUE)
```

.Device

Lists of Open/Active Graphics Devices

Description

A pairlist of the names of open graphics devices is stored in .Devices. The name of the active device (see dev.cur) is stored in .Device. Both are symbols and so appear in the base namespace.

Value

.Device is a length-one character vector.

.Devices is a pairlist of length-one character vectors. The first entry is always "null device", and there are as many entries as the maximal number of graphics devices which have been simultaneously active. If a device has been removed, its entry will be "" until the device number is reused.

Devices may add attributes to the character vector: for example devices which write to a file may record its path in attribute "filepath".
**Description**

*.Machine* is a variable holding information on the numerical characteristics of the machine \( \mathbb{R} \) is running on, such as the largest double or integer and the machine’s precision.

**Usage**

*.Machine*

**Details**

The algorithm is based on Cody’s (1988) subroutine MACHAR. As all current implementations of \( \mathbb{R} \) use 32-bit integers and use IEC 60559 floating-point (double precision) arithmetic, the "integer" and "double" related values are the same for almost all \( \mathbb{R} \) builds.

Note that on most platforms smaller positive values than *.Machine$double.xmin* can occur. On a typical \( \mathbb{R} \) platform the smallest positive double is about 5e−324.

**Value**

A list with components

- **double.eps** the smallest positive floating-point number \( x \) such that \( 1 + x \neq 1 \). It equals \( double.base ^ ulp.digits \) if either \( double.base \) is 2 or \( double.rounding \) is 0; otherwise, it is \( (double.base ^ double.ulp.digits) / 2 \). Normally 2.220446e−16.

- **double.neg.eps** a small positive floating-point number \( x \) such that \( 1 - x \neq 1 \). It equals \( double.base ^ double.neg.ulp.digits \) if \( double.base \) is 2 or \( double.rounding \) is 0; otherwise, it is \( (double.base ^ double.neg.ulp.digits) / 2 \). Normally 1.110223e−16. As \( double.neg.ulp.digits \) is bounded below by \( -(double.digits + 3) \), double.neg.eps may not be the smallest number that can alter 1 by subtraction.

- **double.xmin** the smallest non-zero normalized floating-point number, a power of the radix, i.e., \( double.base ^ double.min.exp \). Normally 2.225074e−308.

- **double.xmax** the largest normalized floating-point number. Typically, it is equal to \( (1 - double.neg.eps) * double.base ^ double.max.exp \), but on some machines it is only the second or third largest such number, being too small by 1 or 2 units in the last digit of the significand. Normally 1.797693e+308. Note that larger unnormalized numbers can occur.

- **double.base** the radix for the floating-point representation: normally 2.

- **double.digits** the number of base digits in the floating-point significand: normally 53.

- **double.rounding** the rounding action, one of 0 if floating-point addition chops; 1 if floating-point addition rounds, but not in the IEEE style; 2 if floating-point addition rounds in the IEEE style;
3 if floating-point addition chops, and there is partial underflow;
4 if floating-point addition rounds, but not in the IEEE style, and there is partial underflow;
5 if floating-point addition rounds in the IEEE style, and there is partial underflow.
Normally 5.

double.guard the number of guard digits for multiplication with truncating arithmetic. It
is 1 if floating-point arithmetic truncates and more than double digits base-
double.base digits participate in the post-normalization shift of the floating-
point significand in multiplication, and 0 otherwise.
Normally 0.

double.ulp.digits
the largest negative integer i such that 1 + double.base ^ i != 1, except that it
is bounded below by -(double.digits + 3). Normally -52.

double.neg.ulp.digits
the largest negative integer i such that 1 -double.base ^ i != 1, except that it
is bounded below by -(double.digits + 3). Normally -53.

double.exponent
the number of bits (decimal places if double.base is 10) reserved for the repre-
sentation of the exponent (including the bias or sign) of a floating-point number.
Normally 11.

double.min.exp the largest in magnitude negative integer i such that double.base ^ i is positive
and normalized. Normally -1022.

double.max.exp
the smallest positive power of double.base that overflows. Normally 1024.

integer.max the largest integer which can be represented. Always \(2^{31} - 1 = 2147483647\).

sizeof.long the number of bytes in a C long type: 4 or 8 (most 64-bit systems, but not
Windows).

sizeof.longlong the number of bytes in a C long long type. Will be zero if there is no such type,
otherwise usually 8.

sizeof.longdouble
the number of bytes in a C long double type. Will be zero if there is no such type
(or its use was disabled when R was built), otherwise possibly 12 (most
32-bit builds) or 16 (most 64-bit builds).

sizeof.pointer the number of bytes in a C SEXP type. Will be 4 on 32-bit builds and 8 on 64-bit
builds of R.

longdouble.eps, longdouble.neg.eps, longdouble.digits, ...
when capabilities("long.double") is true, there are 10 such
"longdouble.<kind>" values, specifying the long double property corresponding to its "double.*" counterpart, above, see also ‘Note’.

Note

In the (typical) case where capabilities("long.double") is true, R uses the long double C type
in quite a few places internally for accumulators in e.g. sum, reading non-integer numeric constants
into (binary) double precision numbers, or arithmetic such as x %% y; also, long double can be read
by readBin.
For this reason, in that case, .Machine contains ten further components, longdouble.eps, *
.neg.eps, *.digits, *.rounding *, guard, *.ulp.digits, *.neg.ulp.digits, *.exponent,
*.min.exp, and *.max.exp, computed entirely analogously to their double.* counterparts, see there.

sizeof.longdouble only tells you the amount of storage allocated for a long double. Often what is stored is the 80-bit extended double type of IEC 60559, padded to the double alignment used on the platform — this seems to be the case for the common R platforms using ix86 and x86_64 chips.

Note that it is legal for a platform to have a long double C type which is identical to the double type — this happens on ARM cpus. In that case capabilities("long.double") will be false but .Machine may contain "longdouble.<kind>" elements.

Source

Uses a C translation of Fortran code in the reference, modified by the R Core Team to defeat over-optimization in modern compilers.

References

See Also

.Platform for details of the platform.

Examples

```r
.Machine
## or for a neat printout
noquote(unlist(format(.Machine)))
```

Platform Specific Variables

Description

.Platform is a list with some details of the platform under which R was built. This provides means to write OS-portable R code.

Usage

.Platform

Value

A list with at least the following components:

- **OS.type**: character string, giving the Operating System (family) of the computer. One of "unix" or "windows".
- **file.sep**: character string, giving the file separator used on your platform: "/" on both Unix-alikes and on Windows (but not on the former port to Classic Mac OS).
.Platform

dynlib.ext character string, giving the file name extension of dynamically loadable libraries, e.g., ".dll" on Windows and ".so" or ".sl" on Unix-alikes. (Note for macOS users: these are shared objects as loaded by dyn.load and not dylibs: see dyn.load.)

GUI character string, giving the type of GUI in use, or "unknown" if no GUI can be assumed. Possible values are for Unix-alikes the values given via the `--g` command-line flag ("X11", "Tk"), "AQUA" (running under R.app on macOS), "Rgui" and "RTerm" (Windows) and perhaps others under alternative front-ends or embedded R.

e endian character string, "big" or "little", giving the 'endianness' of the processor in use. This is relevant when it is necessary to know the order to read/write bytes of e.g. an integer or double from/to a connection: see readBin.

pkgType character string, the preferred setting for options("pkgType"). Values "source", "mac.binary" and "win.binary" are currently in use. This should not be used to identify the OS.

path.sep character string, giving the path separator, used on your platform, e.g., ":" on Unix-alikes and ";" on Windows. Used to separate paths in environment variables such as PATH and TEXINPUTS.

r_arch character string, possibly ".". The name of an architecture-specific directory used in this build of R.

AQUA

.Platform$GUI is set to "AQUA" under the macOS GUI, R.app. This has a number of consequences:

• '/usr/local/bin' is appended to the PATH environment variable.
• the default graphics device is set to quartz.
• selects native (rather than Tk) widgets for the graphics = TRUE options of menu and select.list.
• HTML help is displayed in the internal browser.
• the spreadsheet-like data editor/viewer uses a Quartz version rather than the X11 one.

See Also

R.version and Sys.info give more details about the OS. In particular, R.version$platform is the canonical name of the platform under which R was compiled.

.Machine for details of the arithmetic used, and system for invoking platform-specific system commands.

capabilities and extSoftVersion (and links there) for availability of capabilities partly external to R but used from R functions.

Examples

```r
## Note: this can be done in a system-independent way by dir.exists()
if(.Platform$OS.type == "unix") {
  system.test <- function(...) system(paste("test", ...)) == 0L
  dir.exists2 <- function(dir)
    sapply(dir, function(d) system.test("-d", d))
  dir.exists2(c(R.home(), "/tmp", "-", "/NO")) # > T T T F
}
```
Abbreviate strings to at least `minlength` characters, such that they remain unique (if they were), unless `strict = TRUE`.

**Usage**

```r
abbreviate(names.arg, minlength = 4, use.classes = TRUE,
          dot = FALSE, strict = FALSE,
          method = c("left.kept", "both.sides"), named = TRUE)
```

**Arguments**

- `names.arg`: a character vector of names to be abbreviated, or an object to be coerced to a character vector by `as.character`.
- `minlength`: the minimum length of the abbreviations.
- `use.classes`: logical: should lowercase characters be removed first?
- `dot`: logical: should a dot (".") be appended?
- `strict`: logical: should `minlength` be observed strictly? Note that setting `strict = TRUE` may return non-unique strings.
- `method`: a character string specifying the method used with default "left.kept", see 'Details' below. Partial matches allowed.
- `named`: logical: should `names` (with original vector) be returned.

**Details**

The default algorithm (`method = "left.kept"`) used is similar to that of S. For a single string it works as follows. First spaces at the ends of the string are stripped. Then (if necessary) any other spaces are stripped. Next, lower case vowels are removed followed by lower case consonants. Finally if the abbreviation is still longer than `minlength` upper case letters and symbols are stripped. Characters are always stripped from the end of the strings first. If an element of `names.arg` contains more than one word (words are separated by spaces) then at least one letter from each word will be retained.

Missing (NA) values are unaltered.

If `use.classes` is FALSE then the only distinction is to be between letters and space.

**Value**

A character vector containing abbreviations for the character strings in its first argument. Duplicates in the original `names.arg` will be given identical abbreviations. If any non-duplicated elements have the same `minlength` abbreviations then, if `method = "both.sides"` the basic internal `abbreviate()` algorithm is applied to the characterwise reversed strings; if there are still duplicated abbreviations and if `strict = FALSE` as by default, `minlength` is incremented by one and new abbreviations are found for those elements only. This process is repeated until all unique elements of `names.arg` have unique abbreviations.
If `names` is true, the character version of `names.arg` is attached to the returned value as a `names` attribute: no other attributes are retained.

If a input element contains non-ASCII characters, the corresponding value will be in UTF-8 and marked as such (see `Encoding`).

**Warning**

If `use.classes` is true (the default), this is really only suitable for English, and prior to R 3.3.0 did not work correctly with non-ASCII characters in multibyte locales. It will warn if used with non-ASCII characters (and required to reduce the length).

As from R 3.3.0 the concept of 'vowel' is extended from English vowels by including characters which are accented versions of lower-case English vowels (including 'o with stroke'). Of course, there are languages (even Western European languages such as Welsh) with other vowels.

**See Also**

`substr`.

**Examples**

```r
x <- c("abcd", "efgh", "abce")
abbreviate(x, 2)
abbreviate(x, 2, strict = TRUE) # >> 1st and 3rd are == "ab"

(st.abb <- abbreviate(state.name, 2))
stopifnot(identical(unname(st.abb),
                      abbreviate(state.name, 2, named=FALSE)))
table(nchar(st.abb)) # out of 50, 3 need 4 letters :
as <- abbreviate(state.name, 3, strict = TRUE)
as[which(as == "Mss")]

## and without distinguishing vowels:
st.abb2 <- abbreviate(state.name, 2, FALSE)
cbind(st.abb, st.abb2)[st.abb2 != st.abb, ]

## method = "both.sides" helps: no 4-letters, and only 4 3-letters:
st.ab2 <- abbreviate(state.name, 2, method = "both")
table(nchar(st.ab2))
## Compare the two methods:
cbind(st.abb, st.ab2)
```

---

**agrep**

**Approximate String Matching (Fuzzy Matching)**

**Description**

Searches for approximate matches to `pattern` (the first argument) within each element of the string `x` (the second argument) using the generalized Levenshtein edit distance (the minimal possibly weighted number of insertions, deletions and substitutions needed to transform one string into another).
agrep

Usage

agrep(pattern, x, max.distance = 0.1, costs = NULL,
     ignore.case = FALSE, value = FALSE, fixed = TRUE,
     useBytes = FALSE)

grepl(pattern, x, max.distance = 0.1, costs = NULL,
     ignore.case = FALSE, fixed = TRUE, useBytes = FALSE)

Arguments

pattern     a non-empty character string or a character string containing a regular expression
             (for fixed = FALSE) to be matched. Coerced by as.character to a string if
             possible.
x           character vector where matches are sought. Coerced by as.character to a
             character vector if possible.
max.distance Maximum distance allowed for a match. Expressed either as integer, or as a
             fraction of the pattern length times the maximal transformation cost (will be
             replaced by the smallest integer not less than the corresponding fraction), or a
             list with possible components
             cost: maximum number/fraction of match cost (generalized Levenshtein dis-
                   tance)
             all: maximal number/fraction of all transformations (insertions, deletions and
                   substitutions)
             insertions: maximum number/fraction of insertions
             deletions: maximum number/fraction of deletions
             substitutions: maximum number/fraction of substitutions
             If cost is not given, all defaults to 10%, and the other transformation number
             bounds default to all. The component names can be abbreviated.
costs       a numeric vector or list with names partially matching ‘insertions’,
             ‘deletions’ and ‘substitutions’ giving the respective costs for computing
             the generalized Levenshtein distance, or NULL (default) indicating using unit
             cost for all three possible transformations. Coerced to integer via as.integer
             if possible.
ignore.case if FALSE, the pattern matching is case sensitive and if TRUE, case is ignored
             during matching.
value       if FALSE, a vector containing the (integer) indices of the matches determined is
             returned and if TRUE, a vector containing the matching elements themselves is
             returned.
fixed       logical. If TRUE (default), the pattern is matched literally (as is). Otherwise, it
             is matched as a regular expression.
useBytes    logical. in a multibyte locale, should the comparison be character-by-character
             (the default) or byte-by-byte.

Details

The Levenshtein edit distance is used as measure of approximateness: it is the (possibly cost-
weighted) total number of insertions, deletions and substitutions required to transform one string
into another.
This uses tre by Ville Laurikari (https://laurikari.net/tre/), which supports MBCS character matching.

The main effect of useBytes is to avoid errors/warnings about invalid inputs and spurious matches in multibyte locales. It inhibits the conversion of inputs with marked encodings, and is forced if any input is found which is marked as "bytes" (see Encoding).

Value

grep returns a vector giving the indices of the elements that yielded a match, or, if value is TRUE, the matched elements (after coercion, preserving names but no other attributes).

grep1 returns a logical vector.

Note

Since someone who read the description carelessly even filed a bug report on it, do note that this matches substrings of each element of x (just as grep does) and not whole elements. See also adist in package utils, which optionally returns the offsets of the matched substrings.

Author(s)

Original version in R < 2.10.0 by David Meyer. Current version by Brian Ripley and Kurt Hornik.

See Also

grep, adist. A different interface to approximate string matching is provided by aregexec().

Examples

agrep("lasy", "1 lazy 2")
agrep("lasy", c(" 1 lazy 2", "l lazy 2"), max = list(sub = 0))
agrep("laysy", c("1 lazy", "1", "1 LAZY"), max = 2)
agrep("laysy", c("1 lazy", "1", "1 LAZY"), max = 2, value = TRUE)
agrep("laysy", c("1 lazy", "1", "1 LAZY"), max = 2, ignore.case = TRUE)

all Are All Values True?

Description

Given a set of logical vectors, are all of the values true?

Usage

all(..., na.rm = FALSE)

Arguments

... zero or more logical vectors. Other objects of zero length are ignored, and the rest are coerced to logical ignoring any class.

na.rm logical. If true NA values are removed before the result is computed.
Details

This is a generic function: methods can be defined for it directly or via the \texttt{Summary} group generic. For this to work properly, the arguments \ldots should be unnamed, and dispatch is on the first argument.

Coercion of types other than integer (raw, double, complex, character, list) gives a warning as this is often unintentional.

This is a \textit{primitive} function.

Value

The value is a logical vector of length one.

Let \texttt{x} denote the concatenation of all the logical vectors in \ldots (after coercion), after removing NAs if requested by \texttt{na.rm = TRUE}.

The value returned is \texttt{TRUE} if all of the values in \texttt{x} are \texttt{TRUE} (including if there are no values), and \texttt{FALSE} if at least one of the values in \texttt{x} is \texttt{FALSE}. Otherwise the value is \texttt{NA} (which can only occur if \texttt{na.rm = FALSE} and \ldots contains no \texttt{FALSE} values and at least one \texttt{NA} value).

S4 methods

This is part of the S4 \texttt{Summary} group generic. Methods for it must use the signature \texttt{x, \ldots, na.rm}.

Note

That \texttt{all(logical(0))} is true is a useful convention: it ensures that

\begin{verbatim}
all(all(x), all(y)) == all(x, y)
\end{verbatim}

even if \texttt{x} has length zero.

References

See Also

\texttt{any}, the `complement' of \texttt{all}, and \texttt{stopifnot(*)} which is an \texttt{all(*)} `insurance'.

Examples

\begin{verbatim}
range(x <- sort(round(stats::rnorm(10) - 1.2, 1)))
if(all(x < 0)) cat("all x values are negative\n"

all(logical(0))  # true, as all zero of the elements are true.
\end{verbatim}
all.equal

Test if Two Objects are (Nearly) Equal

Description

all.equal(x,y) is a utility to compare R objects x and y testing ‘near equality’. If they are different, comparison is still made to some extent, and a report of the differences is returned. Do not use all.equal directly in if expressions—either use isTRUE(all.equal(...)) or identical if appropriate.

Usage

all.equal(target, current, ...)

## S3 method for class 'numeric'
all.equal(target, current, 
tolerance = sqrt(.Machine$double.eps), scale = NULL, 
countEQ = FALSE, 
formatFUN = function(err, what) format(err), 
..., check.attributes = TRUE)

## S3 method for class 'list'
all.equal(target, current, ..., 
check.attributes = TRUE, use.names = TRUE)

## S3 method for class 'environment'
all.equal(target, current, all.names=TRUE, ...)

## S3 method for class 'function'
all.equal(target, current, check.environments=TRUE, ...)

## S3 method for class 'POSIXt'
all.equal(target, current, ..., tolerance = 1e-3, scale, 
check.tzone = TRUE)

attr.all.equal(target, current, ..., 
check.attributes = TRUE, check.names = TRUE)

Arguments

target R object.
current other R object, to be compared with target.
... further arguments for different methods, notably the following two, for numerical comparison:
tolerance numeric ≥ 0. Differences smaller than tolerance are not reported. The default value is close to 1.5e-8.
scale NULL or numeric > 0, typically of length 1 or length(target). See ‘Details’.
countEQ logical indicating if the target == current cases should be counted when computing the mean (absolute or relative) differences. The default, FALSE may seem misleading in cases where target and current only differ in a few places; see the extensive example.

formatFUN a function of two arguments, err, the relative, absolute or scaled error, and what, a character string indicating the kind of error; may be used, e.g., to format relative and absolute errors differently.

check.attributes logical indicating if the attributes of target and current (other than the names) should be compared.

use.names logical indicating if list comparison should report differing components by name (if matching) instead of integer index. Note that this comes after ... and so must be specified by its full name.

all.names logical passed to ls indicating if “hidden” objects should also be considered in the environments.

check.environments logical requiring that the environment()s of functions should be compared, too. You may need to set check.environments=FALSE in unexpected cases, such as when comparing two nls() fits.

check.tzone logical indicating if the “tzone” attributes of target and current should be compared.

check.names logical indicating if the names(.) of target and current should be compared.

Details

all.equal is a generic function, dispatching methods on the target argument. To see the available methods, use methods("all.equal"), but note that the default method also does some dispatching, e.g. using the raw method for logical targets.

Remember that arguments which follow ... must be specified by (unabbreviated) name. It is inadvisable to pass unnamed arguments in ... as these will match different arguments in different methods.

Numerical comparisons for scale = NULL (the default) are typically on relative difference scale unless the target values are close to zero: First, the mean absolute difference of the two numerical vectors is computed. If this is smaller than tolerance or not finite, absolute differences are used, otherwise relative differences scaled by the mean absolute target value. Note that these comparisons are computed only for those vector elements where target is not NA and differs from current. If countEQ is true, the equal and NA cases are counted in determining “sample” size.

If scale is numeric (and positive), absolute comparisons are made after scaling (dividing) by scale. For complex target, the modulus (Mod) of the difference is used: all.equal.numeric is called so arguments tolerance and scale are available.

The list method compares components of target and current recursively, passing all other arguments, as long as both are “list-like”, i.e., fulfill either is.vector or is.list.

The environment method works via the list method, and is also used for reference classes (unless a specific all.equal method is defined).

The method for date-time objects uses all.equal.numeric to compare times (in "POSIXct" representation) with a default tolerance of 0.001 seconds, ignoring scale. A time zone mismatch between target and current is reported unless check.tzone = FALSE.

attr.all.equal is used for comparing attributes, returning NULL or a character vector.
all.equal

Value

Either TRUE (NULL for attr.all.equal) or a vector of mode "character" describing the differences between target and current.

References

See Also

identical, isTRUE, ==, and all for exact equality testing.

Examples

```r
all.equal(pi, 355/113)
# not precise enough (default tol) > relative error

d45 <- pi*(1/4 + 1:10)
stopifnot(
  all.equal(tan(d45), rep(1, 10)))  # TRUE, but
  all.equal(tan(d45) == rep(1, 10))  # FALSE, since not exactly
  all.equal(tan(d45), rep(1, 10), tolerance = 0)  # to see difference

## advanced: equality of environments
ae <- all.equal(as.environment("package:stats"),
                asNamespace("stats"))
stopifnot(is.character(ae), length(ae) > 10,
          ## were incorrectly "considered equal" in R <= 3.1.1
          all.equal(asNamespace("stats"), asNamespace("stats")))

## A situation where 'countEQ = TRUE' makes sense:
x1 <- x2 <- (1:100)/10; x2[2] <- 1.1*x1[2]
## 99 out of 100 pairs (x1[i], x2[i]) are equal:
plot(x1,x2, main = "all.equal.numeric() -- not counting equal parts")
all.equal(x1,x2)  ## "Mean relative difference: 0.1"
mtex(taste("all.equal(x1,x2) :", all.equal(x1,x2)), line= -2)
## extract the 'Mean relative difference' as number:
all.eqNum <- function(...) as.numeric(sub(".*:\s+\", '', all.equal(...))))
set.seed(17)
## When x2 is jittered, typically all pairs (x1[i], x2[i]) do differ:
summary(r <- replicate(100, all.eqNum(x1, x2*(1+rnorm(x1)*1e-7))))
mtex(taste("mean(all.equal(x1, x2*(1 + eps_k))) {100 x} Mean rel.diff.=",
signif(mean(r), 3)), line = 3, adj=0)
## With argument countEQ=TRUE, get "the same" (w/o need for jittering):
mtex(taste("all.equal(x1,x2, countEQ=TRUE) ",
signif(all.eqNum(x1,x2, countEQ=TRUE), 3)), line= -6, col=2)

## comparison of date-time objects
now <- Sys.time()
stopifnot( all.equal(now, now + 1e-4)  # TRUE (default tolerance = 0.001 seconds) )
all.equal(now, now + 0.2)
all.equal(now, as.POSIXlt(now, "UTC"))
stopifnot( all.equal(now, as.POSIXlt(now, "UTC"), check.tzone = FALSE)  # TRUE
```
**all.names**

Find All Names in an Expression

**Description**

Return a character vector containing all the names which occur in an expression or call.

**Usage**

```r
all.names(expr, functions = TRUE, max.names = -1L, unique = FALSE)

all.vars(expr, functions = FALSE, max.names = -1L, unique = TRUE)
```

**Arguments**

- `expr`: an expression or call from which the names are to be extracted.
- `functions`: a logical value indicating whether function names should be included in the result.
- `max.names`: the maximum number of names to be returned. -1 indicates no limit (other than vector size limits).
- `unique`: a logical value which indicates whether duplicate names should be removed from the value.

**Details**

These functions differ only in the default values for their arguments.

**Value**

A character vector with the extracted names.

**See Also**

`substitute` to replace symbols with values in an expression.

**Examples**

```r
all.names(expression(sin(x+y)))
all.names(quote(sin(x+y))) # or a call
all.vars(expression(sin(x+y)))
```
any

Are Some Values True?

Description
Given a set of logical vectors, is at least one of the values true?

Usage
any(..., na.rm = FALSE)

Arguments
... zero or more logical vectors. Other objects of zero length are ignored, and the rest are coerced to logical ignoring any class.
na.rm logical. If true NA values are removed before the result is computed.

Details
This is a generic function: methods can be defined for it directly or via the Summary group generic. For this to work properly, the arguments ... should be unnamed, and dispatch is on the first argument.
Coercion of types other than integer (raw, double, complex, character, list) gives a warning as this is often unintentional.
This is a primitive function.

Value
The value is a logical vector of length one.
Let x denote the concatenation of all the logical vectors in ... (after coercion), after removing NAs if requested by na.rm = TRUE.
The value returned is TRUE if at least one of the values in x is TRUE, and FALSE if all of the values in x are FALSE (including if there are no values). Otherwise the value is NA (which can only occur if na.rm = FALSE and ... contains no TRUE values and at least one NA value).

S4 methods
This is part of the S4 Summary group generic. Methods for it must use the signature x, ..., na.rm.

References

all, the ‘complement’ of any.

Examples
range(x <- sort(round(stats::rnorm(10) - 1.2, 1)))
if(any(x < 0)) cat("x contains negative values\n")
aperm

Array Transposition

Description
Transpose an array by permuting its dimensions and optionally resizing it.

Usage
aperm(a, perm, ...)
## Default S3 method:
aperm(a, perm = NULL, resize = TRUE, ...)
## S3 method for class 'table'
aperm(a, perm = NULL,resize = TRUE, keep.class = TRUE, ...)

Arguments
a the array to be transposed.
perm the subscript permutation vector, usually a permutation of the integers 1:n, where n is the number of dimensions of a. When a has named dimnames, it can be a character vector of length n giving a permutation of those names. The default (used whenever perm has zero length) is to reverse the order of the dimensions.
resize a flag indicating whether the vector should be resized as well as having its elements reordered (default TRUE).
keep.class logical indicating if the result should be of the same class as a.
... potential further arguments of methods.

Value
A transposed version of array a, with subscripts permuted as indicated by the array perm. If resize is TRUE, the array is reshaped as well as having its elements permuted, the dimnames are also permuted; if resize = FALSE then the returned object has the same dimensions as a, and the dimnames are dropped. In each case other attributes are copied from a.

The function t provides a faster and more convenient way of transposing matrices.

Author(s)
Jonathan Rougier, <J.C.Rougier@durham.ac.uk> did the faster C implementation.

t, to transpose matrices.
Examples

# interchange the first two subscripts on a 3-way array x
x <- array(1:24, 2:4)
x <- aperm(x, c(2,1,3))
stopifnot(t(xt[,2]) == x[,2],
t(xt[,3]) == x[,3],
t(xt[,4]) == x[,4])

UCB <- aperm(UCBAdmissions, c(2,1,3))
UCB[,1]
summary(UCB) # UCB is still a contingency table

---

**append**

**Vector Merging**

**Description**

Add elements to a vector.

**Usage**

```r
append(x, values, after = length(x))
```

**Arguments**

- `x`: the vector the values are to be appended to.
- `values`: to be included in the modified vector.
- `after`: a subscript, after which the values are to be appended.

**Value**

A vector containing the values in `x` with the elements of `values` appended after the specified element of `x`.

**References**

**Examples**

```r
append(1:5, 0:1, after = 3)
```
apply

Apply Functions Over Array Margins

Description

Returns a vector or array or list of values obtained by applying a function to margins of an array or matrix.

Usage

apply(X, MARGIN, FUN, ..., simplify = TRUE)

Arguments

X
an array, including a matrix.

MARGIN
a vector giving the subscripts which the function will be applied over. E.g., for a matrix 1 indicates rows, 2 indicates columns, c(1,2) indicates rows and columns. Where X has named dimnames, it can be a character vector selecting dimension names.

FUN
the function to be applied: see ‘Details’. In the case of functions like +, %*%, etc., the function name must be backquoted or quoted.

... optional arguments to FUN.

simplify a logical indicating whether results should be simplified if possible.

Details

If X is not an array but an object of a class with a non-null dim value (such as a data frame), apply attempts to coerce it to an array via as.matrix if it is two-dimensional (e.g., a data frame) or via as.array.

FUN is found by a call to match.fun and typically is either a function or a symbol (e.g., a backquoted name) or a character string specifying a function to be searched for from the environment of the call to apply.

Arguments in ... cannot have the same name as any of the other arguments, and care may be needed to avoid partial matching to MARGIN or FUN. In general-purpose code it is good practice to name the first three arguments if ... is passed through: this both avoids partial matching to MARGIN or FUN and ensures that a sensible error message is given if arguments named X, MARGIN or FUN are passed through ...

Value

If each call to FUN returns a vector of length n, and simplify is TRUE, then apply returns an array of dimension c(n, dim(X)[MARGIN]) if n > 1. If n equals 1, apply returns a vector if MARGIN has length 1 and an array of dimension dim(X)[MARGIN] otherwise. If n is 0, the result has length 0 but not necessarily the ‘correct’ dimension.

If the calls to FUN return vectors of different lengths, or if simplify is FALSE, apply returns a list of length prod(dim(X)[MARGIN]) with dim set to MARGIN if this has length greater than one.

In all cases the result is coerced by as.vector to one of the basic vector types before the dimensions are set, so that (for example) factor results will be coerced to a character array.

Examples

```r
## Compute row and column sums for a matrix:
x <- cbind(x1 = 3, x2 = c(4:1, 2:5))
dimnames(x)[[1]] <- letters[1:8]
apply(x, 2, mean, trim = .2)
col.sums <- apply(x, 2, sum)
row.sums <- apply(x, 1, sum)
rbind(cbind(x, Rtot = row.sums), Ctot = c(col.sums, sum(col.sums)))

stopifnot(apply(x, 2, is.vector))

## Sort the columns of a matrix
apply(x, 2, sort)

## keeping named dimnames
names(dimnames(x)) <- c("row", "col")
x3 <- array(x, dim = c(dim(x), 3),
            dimnames = c(dimnames(x), list(C = paste0("cop.",1:3))))
identical(x, apply(x, 2, identity))
identical(x3, apply(x3, 2:3, identity))

##- function with extra args:
cave <- function(x, c1, c2) c(mean(x[c1]), mean(x[c2]))
apply(x, 1, cave, c1 = "x1", c2 = c("x1","x2"))

ma <- matrix(c(1:4, 1, 6:8), nrow = 2)

apply(ma, 1, table)  #---> a list of length 2
apply(ma, 1, stats::quantile)  # 5 x n matrix with rownames

stopifnot(dim(ma) == dim(apply(ma, 1:2, sum)))

## Example with different lengths for each call
z <- array(1:24, dim = 2:4)
zseq <- apply(z, 1:2, function(x) seq_len(max(x)))
zseq  # a 2 x 3 matrix
typeof(zseq)  # list
dim(zseq)  # 2 3
zseq[1,]
apply(z, 3, function(x) seq_len(max(x)))
# a list without a dim attribute
```
**Description**

Displays the argument names and corresponding default values of a function or primitive.

**Usage**

`args(name)`

**Arguments**

- `name` a function (a closure or a primitive). If `name` is a character string then the function with that name is found and used.

**Details**

This function is mainly used interactively to print the argument list of a function. For programming, consider using `formals` instead.

**Value**

- For a closure, a closure with identical formal argument list but an empty (NULL) body.
- For a primitive, a closure with the documented usage and NULL body. Note that some primitives do not make use of named arguments and match by position rather than name.
- NULL in case of a non-function.

**References**

**See Also**

`formals`, `help`; `str` also prints the argument list of a function.

**Examples**

```r
## "regular" (non-primitive) functions "print their arguments"
## (by returning another function with NULL body which you also see):
args(ls)
args(graphics::plot.default)
utils::str(ls) # (just "prints": does not show a NULL)

## You can also pass a string naming a function.
args("scan")
## ...but :: package specification doesn't work in this case.
tryCatch(args("graphics::plot.default"), error = print)

## As explained above, args() gives a function with empty body:
list(is.f = is.function(args(scan)), body = body(args(scan)))

## Primitive functions mostly behave like non-primitive functions.
args(c)
args('+')
## primitive functions without well-defined argument list return NULL:
args('if')
```
Description

These unary and binary operators perform arithmetic on numeric or complex vectors (or objects which can be coerced to them).

Usage

+ x  
- x  
x + y  
x - y  
x * y  
x / y  
x ^ y  
x %% y  
x %/% y

Arguments

x, y  
numeric or complex vectors or objects which can be coerced to such, or other objects for which methods have been written.

Details

The unary and binary arithmetic operators are generic functions: methods can be written for them individually or via the Ops group generic function. (See Ops for how dispatch is computed.)

If applied to arrays the result will be an array if this is sensible (for example it will not if the recycling rule has been invoked).

Logical vectors will be coerced to integer or numeric vectors, FALSE having value zero and TRUE having value one.

1 ^ y and y ^ 0 are 1, always. x ^ y should also give the proper limit result when either (numeric) argument is infinite (one of Inf or -Inf).

Objects such as arrays or time-series can be operated on this way provided they are conformable.

For double arguments, % can be subject to catastrophic loss of accuracy if x is much larger than y, and a warning is given if this is detected.

%% and x %/% y can be used for non-integer y, e.g. 1 %/% 0.2, but the results are subject to representation error and so may be platform-dependent. Because the IEC 60559 representation of 0.2 is a binary fraction slightly larger than 0.2, the answer to 1 %/% 0.2 should be 4 but most platforms give 5.

Users are sometimes surprised by the value returned, for example why (-8)^(1/3) is NaN. For double inputs, R makes use of IEC 60559 arithmetic on all platforms, together with the C system function ‘pow’ for the ^ operator. The relevant standards define the result in many corner cases. In particular, the result in the example above is mandated by the C99 standard. On many Unix-alike systems the command man pow gives details of the values in a large number of corner cases.

Arithmetic on type double in R is supposed to be done in ‘round to nearest, ties to even’ mode, but this does depend on the compiler and FPU being set up correctly.
Arithmetic

Value

Unary + and unary - return a numeric or complex vector. All attributes (including class) are preserved if there is no coercion: logical x is coerced to integer and names, dims and dimnames are preserved.

The binary operators return vectors containing the result of the element by element operations. If involving a zero-length vector the result has length zero. Otherwise, the elements of shorter vectors are recycled as necessary (with a warning when they are recycled only fractionally). The operators are + for addition, - for subtraction, * for multiplication, / for division and ^ for exponentiation.

%% indicates x mod y (“x modulo y”) and %/% indicates integer division. It is guaranteed that

\[ x == (x \%\% y) + y * (x \div\% y) \] (up to rounding error)

unless y == 0 where the result of %% is \texttt{NA\_integer\_} or \texttt{NaN} (depending on the \texttt{typeof} of the arguments) or for some non-finite arguments, e.g., when the RHS of the identity above amounts to \texttt{Inf -Inf}.

If either argument is complex the result will be complex, otherwise if one or both arguments are numeric, the result will be numeric. If both arguments are of type \texttt{integer}, the type of the result of / and ^ is \texttt{numeric} and for the other operators it is \texttt{integer} (with overflow, which occurs at \pm (2^{31} - 1), returned as \texttt{NA\_integer\_} with a warning).

The rules for determining the attributes of the result are rather complicated. Most attributes are taken from the longer argument. Names will be copied from the first if it is the same length as the answer, otherwise from the second if that is. If the arguments are the same length, attributes will be copied from both, with those of the first argument taking precedence when the same attribute is present in both arguments. For time series, these operations are allowed only if the series are compatible, when the class and \texttt{tsp} attribute of whichever is a time series (the same, if both are) are used. For arrays (and an array result) the dimensions and dimnames are taken from first argument if it is an array, otherwise the second.

S4 methods

These operators are members of the S4 \texttt{Arith} group generic, and so methods can be written for them individually as well as for the group generic (or the \texttt{Ops} group generic), with arguments \texttt{c(e1,e2)} (with e2 missing for a unary operator).

Implementation limits

\texttt{R} is dependent on OS services (and they on FPUs) for floating-point arithmetic. On all current \texttt{R} platforms IEC 60559 (also known as IEEE 754) arithmetic is used, but some things in those standards are optional. In particular, the support for \texttt{denormal} aka \texttt{subnormal} numbers (those outside the range given by \texttt{.Machine}) may differ between platforms and even between calculations on a single platform.

Another potential issue is signed zeroes: on IEC 60559 platforms there are two zeroes with internal representations differing by sign. Where possible \texttt{R} treats them as the same, but for example direct output from C code often does not do so and may output ‘-0.0’ (and on Windows whether it does so or not depends on the version of Windows). One place in \texttt{R} where the difference might be seen is in division by zero: 1/x is \texttt{Inf} or -\texttt{Inf} depending on the sign of zero x. Another place is \texttt{identical(0,-0,num.eq = FALSE)}.

Note

All logical operations involving a zero-length vector have a zero-length result.
The binary operators are sometimes called as functions as e.g. `\&` `(x, y)`: see the description of how argument-matching is done in `Ops`.

`**` is translated in the parser to `^`, but this was undocumented for many years. It appears as an index entry in Becker et al (1988), pointing to the help for `Deprecated` but is not actually mentioned on that page. Even though it had been deprecated in S for 20 years, it was still accepted in R in 2008.

Examples

```r
x <- -1:12
x + 1
2 * x + 3
x %% 2 #-- is periodic
x %/% 5
x %% Inf # now is defined by limit (gave NaN in earlier versions of R)
```

array

Multi-way Arrays

Description

Creates or tests for arrays.

Usage

```r
array(data = NA, dim = length(data), dimnames = NULL)
as.array(x, ...)
is.array(x)
```
Arguments

data a vector (including a list or expression vector) giving data to fill the array. 
Non-atomic classed objects are coerced by as.vector.
dim the dim attribute for the array to be created, that is an integer vector of length 
one or more giving the maximal indices in each dimension.
dimnames either NULL or the names for the dimensions. This must a list (or it will be 
ignored) with one component for each dimension, either NULL or a character 
vector of the length given by dim for that dimension. The list can be named, and 
the list names will be used as names for the dimensions. If the list is shorter than 
the number of dimensions, it is extended by NULLs to the length required.
x an R object.
... additional arguments to be passed to or from methods.

Details

An array in R can have one, two or more dimensions. It is simply a vector which is stored with addi-
tional attributes giving the dimensions (attribute "dim") and optionally names for those dimensions 
(attribute "dimnames").

A two-dimensional array is the same thing as a matrix.

One-dimensional arrays often look like vectors, but may be handled differently by some functions:
str does distinguish them in recent versions of R.

The "dim" attribute is an integer vector of length one or more containing non-negative values: the 
product of the values must match the length of the array.

The "dimnames" attribute is optional: if present it is a list with one component for each dimension, 
either NULL or a character vector of the length given by the element of the "dim" attribute for that 
dimension.

is.array is a primitive function.

For a list array, the print methods prints entries of length not one in the form ‘integer,7’ indicating 
the type and length.

Value

array returns an array with the extents specified in dim and naming information in dimnames. The 
values in data are taken to be those in the array with the leftmost subscript moving fastest. If there 
are too few elements in data to fill the array, then the elements in data are recycled. If data has 
length zero, NA of an appropriate type is used for atomic vectors (0 for raw vectors) and NULL for 
lists.

Unlike matrix, array does not currently remove any attributes left by as.vector from a classed 
list data, so can return a list array with a class attribute.

as.array is a generic function for coercing to arrays. The default method does so by attaching a 
dim attribute to it. It also attaches dimnames if x has names. The sole purpose of this is to make it 
possible to access the dim[names] attribute at a later time.

is.array returns TRUE or FALSE depending on whether its argument is an array (i.e., has a dim 
attribute of positive length) or not. It is generic: you can write methods to handle specific classes of 
objects, see InternalMethods.

Note

is.array is a primitive function.

#[1,] 1 3 2 1
#[2,] 2 1 3 2

---

as.data.frame Coerce to a Data Frame

Description

Functions to check if an object is a data frame, or coerce it if possible.

Usage

as.data.frame(x, row.names = NULL, optional = FALSE, ...)

## S3 method for class 'character'
as.data.frame(x, ..., 
  stringsAsFactors = FALSE)

## S3 method for class 'list'
as.data.frame(x, row.names = NULL, optional = FALSE, ..., 
  cut.names = FALSE, col.names = names(x), fix.empty.names = TRUE, 
  check.names = !optional, 
  stringsAsFactors = FALSE)

## S3 method for class 'matrix'
as.data.frame(x, row.names = NULL, optional = FALSE, 
  make.names = TRUE, ..., 
  stringsAsFactors = FALSE)

is.data.frame(x)

Arguments

x any R object.

row.names NULL or a character vector giving the row names for the data frame. Missing values are not allowed.
as.data.frame

optional logical. If TRUE, setting row names and converting column names (to syntactic names: see make.names) is optional. Note that all of R's base package as.data.frame() methods use optional only for column names treatment, basically with the meaning of data.frame(*,check.names = !optional). See also the make.names argument of the matrix method.

... additional arguments to be passed to or from methods.

stringsAsFactors logical: should the character vector be converted to a factor?

cut.names logical or integer; indicating if column names with more than 256 (or cut.names if that is numeric) characters should be shortened (and the last 6 characters replaced by "...").

col.names (optional) character vector of column names.

fix.empty.names logical indicating if empty column names, i.e., "" should be fixed up (in data.frame) or not.

check.names logical; passed to the data.frame() call.

make.names a logical, i.e., one of FALSE,NA,TRUE, indicating what should happen if the row names (of the matrix x) are invalid. If they are invalid, the default, TRUE, calls make.names(*,unique=TRUE): make.names=NA will use "automatic" row names and a FALSE value will signal an error for invalid row names.

Details

as.data.frame is a generic function with many methods, and users and packages can supply further methods. For classes that act as vectors, often a copy of as.data.frame.vector will work as the method.

If a list is supplied, each element is converted to a column in the data frame. Similarly, each column of a matrix is converted separately. This can be overridden if the object has a class which has a method for as.data.frame: two examples are matrices of class "model.matrix" (which are included as a single column) and list objects of class "POSIXlt" which are coerced to class "POSIXct".

Arrays can be converted to data frames. One-dimensional arrays are treated like vectors and two-dimensional arrays like matrices. Arrays with more than two dimensions are converted to matrices by ‘flattening’ all dimensions after the first and creating suitable column labels.

Character variables are converted to factor columns unless protected by I.

If a data frame is supplied, all classes preceding "data.frame" are stripped, and the row names are changed if that argument is supplied.

If row.names = NULL, row names are constructed from the names or dimnames of x, otherwise are the integer sequence starting at one. Few of the methods check for duplicated row names. Names are removed from vector columns unless I.

Value

as.data.frame returns a data frame, normally with all row names "" if optional = TRUE.

is.data.frame returns TRUE if its argument is a data frame (that is, has "data.frame" amongst its classes) and FALSE otherwise.

`data.frame`, `as.data.frame.table` for the table method (which has additional arguments if called directly).

---

**as.Date**  
*Date Conversion Functions to and from Character*

**Description**

Functions to convert between character representations and objects of class "Date" representing calendar dates.

**Usage**

```r
as.Date(x, ...)  
## S3 method for class 'character'
as.Date(x, format, tryFormats = c("%Y-%m-%d", "%Y/%m/%d"),  
        optional = FALSE, ...)
## S3 method for class 'numeric'
as.Date(x, origin, ...)
## S3 method for class 'POSIXct'
as.Date(x, tz = "UTC", ...)

## S3 method for class 'Date'
format(x, ...)

## S3 method for class 'Date'
as.character(x, ...)
```

**Arguments**

- **x**: an object to be converted.
- **format**: character string. If not specified, it will try tryFormats one by one on the first non-NA element, and give an error if none works. Otherwise, the processing is via `strptime()` whose help page describes available conversion specifications.
- **tryFormats**: character vector of format strings to try if format is not specified.
- **optional**: logical indicating to return NA (instead of signalling an error) if the format guessing does not succeed.
- **origin**: a Date object, or something which can be coerced by `as.Date(origin,...)` to such an object.
- **tz**: a time zone name.
- **...**: further arguments to be passed from or to other methods, including format for `as.character` and `as.Date` methods.
Details

The usual vector re-cycling rules are applied to x and format so the answer will be of length that of the longer of the vectors.

Locale-specific conversions to and from character strings are used where appropriate and available. This affects the names of the days and months.

The `as.Date` methods accept character strings, factors, logical NA and objects of classes "POSIXt" and "POSIXct". (The last is converted to days by ignoring the time after midnight in the representation of the time in specified time zone, default UTC.) Also objects of class "date" (from package `date`) and “dates” (from package `chron`). Character strings are processed as far as necessary for the format specified: any trailing characters are ignored.

`as.Date` will accept numeric data (the number of days since an epoch), but only if `origin` is supplied.

The `format` and `as.character` methods ignore any fractional part of the date.

Value

The `format` and `as.character` methods return a character vector representing the date. NA dates are returned as `NA_character_`.

The `as.Date` methods return an object of class “Date”.

Conversion from other Systems

Most systems record dates internally as the number of days since some origin, but this is fraught with problems, including

- Is the origin day 0 or day 1? As the ‘Examples’ show, Excel manages to use both choices for its two date systems.

- If the origin is far enough back, the designers may show their ignorance of calendar systems. For example, Excel’s designer thought 1900 was a leap year (claiming to copy the error from earlier DOS spreadsheets), and Matlab’s designer chose the non-existent date of ‘January 0, 0000’ (there is no such day), not specifying the calendar. (There is such a year in the ‘Gregorian’ calendar as used in ISO 8601:2004, but that does say that it is only to be used for years before 1582 with the agreement of the parties in information exchange.)

The only safe procedure is to check the other systems values for known dates: reports on the Internet (including R-help) are more often wrong than right.

Note

The default formats follow the rules of the ISO 8601 international standard which expresses a day as "2001-02-03".

If the date string does not specify the date completely, the returned answer may be system-specific. The most common behaviour is to assume that a missing year, month or day is the current one. If it specifies a date incorrectly, reliable implementations will give an error and the date is reported as NA. Unfortunately some common implementations (such as ‘glibc’) are unreliable and guess at the intended meaning.

Years before 1CE (aka 1AD) will probably not be handled correctly.
as.Date

Date for details of the date class; locales to query or set a locale.

Your system’s help pages on strftime and strptime to see how to specify their formats. Windows users will find no help page for strptime: code based on ‘glibc’ is used (with corrections), so all the format specifiers described here are supported, but with no alternative number representation nor era available in any locale.

Examples

## locale-specific version of the date
format(Sys.Date(), "%a %b %d")

## read in date info in format 'ddddmmmm yyyy'
## This will give NA(s) in some locales; setting the C locale
## as in the commented lines will overcome this on most systems.
## lct <- Sys.getlocale("LC_TIME"); Sys.setlocale("LC_TIME", "C")
x <- c("1jan1960", "2jan1960", "31mar1960", "30jul1960")
z <- as.Date(x, "%d%b%Y")
## Sys.setlocale("LC_TIME", lct)
z

## read in date/time info in format 'm/d/y'
dates <- c("02/27/92", "02/27/92", "01/14/92", "02/28/92", "02/01/92")
as.Date(dates, "%m/%d/%y")

## date given as number of days since 1900-01-01 (a date in 1989)
as.Date(32768, origin = "1900-01-01")
## Excel is said to use 1900-01-01 as day 1 (Windows default) or
## 1904-01-01 as day 0 (Mac default), but this is complicated by Excel
## incorrectly treating 1900 as a leap year.
## So for dates (post-1901) from Windows Excel
as.Date(35981, origin = "1899-12-30") # 1998-07-05
## and Mac Excel
as.Date(34519, origin = "1904-01-01") # 1998-07-05
## (these values come from http://support.microsoft.com/kb/214330)

## Experiment shows that Matlab’s origin is 719529 days before ours,
## (it takes the non-existent 0000-01-01 as day 1)
## so Matlab day 734373 can be imported as
as.Date(734373, origin = "1970-01-01") - 719529 # 2010-08-23
## (value from

## Time zone effect
z <- ISOdate(2010, 04, 13, c(0,12)) # midnight and midday UTC
as.Date(z) # in UTC
## these time zone names are common
as.Date(z, tz = "NZ")
as.Date(z, tz = "HST") # Hawaii
as.environment

Coerce to an Environment Object

Description
A generic function coercing an R object to an environment. A number or a character string is converted to the corresponding environment on the search path.

Usage
as.environment(x)

Arguments
x
an R object to convert. If it is already an environment, just return it. If it is a positive number, return the environment corresponding to that position on the search list. If it is -1, the environment it is called from. If it is a character string, match the string to the names on the search list.
If it is a list, the equivalent of list2env(x, parent = emptyenv()) is returned.
If is.object(x) is true and it has a class for which an as.environment method is found, that is used.

Details
This is a primitive generic function: you can write methods to handle specific classes of objects, see InternalMethods.

Value
The corresponding environment object.

Author(s)
John Chambers

See Also
environment for creation and manipulation, search; list2env.

Examples
as.environment(1) ## the global environment
identical(globalenv(), as.environment(1)) ## is TRUE
try( ## <<- stats need not be attached
    as.environment("package:stats")
)ee <- as.environment(list(a = "A", b = pi, ch = letters[1:8]))
ls(ee) # names of objects in ee
utils::ls.str(ee)
as.function  Convert Object to Function

Description

as.function is a generic function which is used to convert objects to functions.

as.function.default works on a list x, which should contain the concatenation of a formal argument list and an expression or an object of mode "call" which will become the function body. The function will be defined in a specified environment, by default that of the caller.

Usage

as.function(x, ...)  
## Default S3 method:  
as.function(x, envir = parent.frame(), ...)  

Arguments

x  object to convert, a list for the default method.  
...  additional arguments, depending on object  
envir  environment in which the function should be defined

Value

The desired function.

Note

For ancient historical reasons, envir = NULL uses the global environment rather than the base environment. Please use envir = globalenv() instead if this is what you want, as the special handling of NULL may change in a future release.

as.POSIX*

Date-time Conversion Functions

Description

Functions to manipulate objects of classes "POSIXlt" and "POSIXct" representing calendar dates and times.

Usage

as.POSIXct(x, tz = "", ...)  
as.POSIXlt(x, tz = "", ...)  
## S3 method for class 'character'  
as.POSIXlt(x, tz = "", format,  
tryFormats = c("%Y-%m-%d %H:%M:%OS",  
"%Y/%m/%d %H:%M:%OS",  
"%Y-%m-%d %H:%M",  
"%Y/%m/%d %H:%M",  
"%Y-%m-%d",  
"%Y/%m/%d"),  
optional = FALSE, ...)  
## Default S3 method:  
as.POSIXlt(x, tz = "", ...)  
## S3 method for class 'numeric'  
as.POSIXlt(x, tz = "", origin, ...)  

## S3 method for class 'POSIXlt'  
as.double(x, ...)  

Arguments

x  
R object to be converted.

tz  
time zone specification to be used for the conversion, if one is required. System-specific (see time zones), but "" is the current time zone, and "GMT" is UTC (Universal Time, Coordinated). Invalid values are most commonly treated as UTC, on some platforms with a warning.

...  
further arguments to be passed to or from other methods.

format  
character string giving a date-time format as used by strftime.

tryFormats  
character vector of format strings to try if format is not specified.

optional  
logical indicating to return NA (instead of signalling an error) if the format guessing does not succeed.

origin  
a date-time object, or something which can be coerced by as.POSIXct(tz = "GMT") to such an object.
Details

The `as.POSIXlt` functions convert an object to one of the two classes used to represent date/times (calendar dates plus time to the nearest second). They can convert objects of the other class and of class "Date" to these classes. Dates without times are treated as being at midnight UTC.

They can also convert character strings of the formats "2001-02-03" and "2001/02/03" optionally followed by white space and a time in the format "14:52" or "14:52:03". (Formats such as "01/02/03" are ambiguous but can be converted via a format specification by `strptime`.) Fractional seconds are allowed. Alternatively, `format` can be specified for character vectors or factors: if it is not specified and no standard format works for all non-NA inputs an error is thrown.

If `format` is specified, remember that some of the format specifications are locale-specific, and you may need to set the `LC_TIME` category appropriately via `Sys.setlocale`. This most often affects the use of %b, %B (month names) and %p (AM/PM).

Logical NAs can be converted to either of the classes, but no other logical vectors can be. If you are given a numeric time as the number of seconds since an epoch, see the examples.

Character input is first converted to class "POSIXlt" by `strptime`: numeric input is first converted to "POSIXct". Any conversion that needs to go between the two date-time classes requires a time zone: conversion from "POSIXlt" to "POSIXct" will validate times in the selected time zone. One issue is what happens at transitions to and from DST, for example in the UK

```r
as.POSIXct(strptime("2011-03-27 01:30:00", "%Y-%m-%d %H:%M:%S"))
as.POSIXct(strptime("2010-10-31 01:30:00", "%Y-%m-%d %H:%M:%S"))
```

are respectively invalid (the clocks went forward at 1:00 GMT to 2:00 BST) and ambiguous (the clocks went back at 2:00 BST to 1:00 GMT). What happens in such cases is OS-specific: one should expect the first to be NA, but the second could be interpreted as either BST or GMT (and common OSes give both possible values). Note too (see `strftime`) that OS facilities may not format invalid times correctly.

Value

`as.POSIXct` and `as.POSIXlt` return an object of the appropriate class. If `tz` was specified, `as.POSIXlt` will give an appropriate "tzone" attribute. Date-times known to be invalid will be returned as NA.

Note

Some of the concepts used have to be extended backwards in time (the usage is said to be 'proleptic'). For example, the origin of time for the "POSIXct" class, '1970-01-01 00:00:00 UTC', is before UTC was defined. More importantly, conversion is done assuming the Gregorian calendar which was introduced in 1582 and not used universally until the 20th century. One of the re-interpretations assumed by ISO 8601:2004 is that there was a year zero, even though current year numbering (and zero) is a much later concept (525 AD for year numbers from 1 AD).

Conversions between "POSIXlt" and "POSIXct" of future times are speculative except in UTC. The main uncertainty is in the use of and transitions to/from DST (most systems will assume the continuation of current rules but these can be changed at short notice).

If you want to extract specific aspects of a time (such as the day of the week) just convert it to class "POSIXlt" and extract the relevant component(s) of the list, or if you want a character representation (such as a named day of the week) use the `format` method.

If a time zone is needed and that specified is invalid on your system, what happens is system-specific but attempts to set it will probably be ignored.
Conversion from character needs to find a suitable format unless one is supplied (by trying common formats in turn): this can be slow for long inputs.

}

AsIs

Inhibit Interpretation/Conversion of Objects

Description
Change the class of an object to indicate that it should be treated 'as is'.

Usage
I(x)

Arguments
x
an object

Details
Function I has two main uses.

- In function data.frame. Protecting an object by enclosing it in I() in a call to data.frame inhibits the conversion of character vectors to factors and the dropping of names, and ensures that matrices are inserted as single columns. I can also be used to protect objects which are to be added to a data frame, or converted to a data frame via as.data.frame. It achieves this by prepending the class "AsIs" to the object's classes. Class "AsIs" has a few of its own methods, including for [], as.data.frame, print and format.

- In function formula. There it is used to inhibit the interpretation of operators such as "+", "-", "*" and "^" as formula operators, so they are used as arithmetical operators. This is interpreted as a symbol by terms.formula.

Value
A copy of the object with class "AsIs" prepended to the class(es).

References

See Also
data.frame, formula
Description

Split an array or matrix by its margins.

Usage

```r
asplit(x, MARGIN)
```

Arguments

- `x` an array, including a matrix.
- `MARGIN` a vector giving the margins to split by. E.g., for a matrix 1 indicates rows, 2 indicates columns, `c(1,2)` indicates rows and columns. Where `x` has named dimnames, it can be a character vector selecting dimension names.

Details

The values of the splits can also be obtained (less efficiently) by `split(x, slice.index(x,MARGIN))`.

`apply` always simplifies common length results, so attempting to split via `apply(x,MARGIN,identity)` does not work (as it simply gives `x`). By chaining `asplit` with `lapply` or `vapply`, one can obtain variants of `apply` which do not auto-simplify.

Value

A “list array” with dimension `dv` and each element an array of dimension `de` and dimnames preserved as available, where `dv` and `de` are, respectively, the dimensions of `x` included and not included in `MARGIN`.

Examples

```r
## A 3-dimensional array of dimension 2 x 3 x 4:
D <- 2 : 4
x <- array(seq_len(prod(D)), D)
x
## Splitting by margin 2 gives a 1-d list array of length 3
## consisting of 2 x 4 arrays:
asplit(x, 2)
## Splitting by margins 1 and 2 gives a 2 x 3 list array
## consisting of 1-d arrays of length 4:
asplit(x, c(1, 2))
## Compare to
split(x, slice.index(x, c(1, 2)))

## A 2 x 3 matrix:
(x <- matrix(1 : 6, 2, 3))
## To split `x` by its rows, one can use
asplit(x, 1)
## or less efficiently
```
assign

Assign a Value to a Name

Description
Assign a value to a name in an environment.

Usage
assign(x, value, pos = -1, envir = as.environment(pos),
    inherits = FALSE, immediate = TRUE)

Arguments
x  a variable name, given as a character string. No coercion is done, and the first
    element of a character vector of length greater than one will be used, with a
    warning.
value a value to be assigned to x.
pos where to do the assignment. By default, assigns into the current environment.
    See ‘Details’ for other possibilities.
envir the environment to use. See ‘Details’.
inherits should the enclosing frames of the environment be inspected?
immediate an ignored compatibility feature.

Details
There are no restrictions on the name given as x: it can be a non-syntactic name (see make.names).
The pos argument can specify the environment in which to assign the object in any of several
ways: as -1 (the default), as a positive integer (the position in the search list); as the character
string name of an element in the search list; or as an environment (including using sys.frame to
access the currently active function calls). The envir argument is an alternative way to specify an
environment, but is primarily for back compatibility.
assign does not dispatch assignment methods, so it cannot be used to set elements of vectors,
names, attributes, etc.
Note that assignment to an attached list or data frame changes the attached copy and not the original
object: see attach and with.

Value
This function is invoked for its side effect, which is assigning value to the variable x. If no envir
is specified, then the assignment takes place in the currently active environment.
If inherits is TRUE, enclosing environments of the supplied environment are searched until the
variable x is encountered. The value is then assigned in the environment in which the variable is
encountered (provided that the binding is not locked: see lockBinding; if it is, an error is signaled).
If the symbol is not encountered then assignment takes place in the user’s workspace (the global
environment).
If inherits is FALSE, assignment takes place in the initial frame of envir, unless an existing binding is locked or there is no existing binding and the environment is locked (when an error is signaled).

<-, get, the inverse of assign(), exists, environment.

Examples

```r
for(i in 1:6) { #-- Create objects 'r.1', 'r.2', ... 'r.6' --
  nam <- paste("r", i, sep = ".")
  assign(nam, 1:i)
}
ls(pattern = "^r..$")

##-- Global assignment within a function:
myf <- function(x) {
  innerf <- function(x) assign("Global.res", x^2, envir = .GlobalEnv)
  innerf(x+1)
}
myf(3)
Global.res # 16

a <- 1:4
assign("a[1]", 2)
a[1] == 2 # FALSE
get("a[1]") == 2 # TRUE
```

assignOps

Assignment Operators

Description

Assign a value to a name.

Usage

```
x <- value
x <<- value
value -> x
value ->> x
x = value
```
Arguments

\( \text{x} \)  

a variable name (possibly quoted).

\( \text{value} \)  

a value to be assigned to \( \text{x} \).

Details

There are three different assignment operators: two of them have leftwards and rightwards forms. The operators \(<-\) and \(=\) assign into the environment in which they are evaluated. The operator \(<-\) can be used anywhere, whereas the operator \(=\) is only allowed at the top level (e.g., in the complete expression typed at the command prompt) or as one of the subexpressions in a braced list of expressions.

The operators \(<<-\) and \(->>\) are normally only used in functions, and cause a search to be made through parent environments for an existing definition of the variable being assigned. If such a variable is found (and its binding is not locked) then its value is redefined, otherwise assignment takes place in the global environment. Note that their semantics differ from that in the S language, but are useful in conjunction with the scoping rules of R. See 'The R Language Definition' manual for further details and examples.

In all the assignment operator expressions, \( \text{x} \) can be a name or an expression defining a part of an object to be replaced (e.g., \( \text{z[[1]]} \)). A syntactic name does not need to be quoted, though it can be (preferably by \texttt{backticks}).

The leftwards forms of assignment \(<-\) \(<<-\) group right to left, the other from left to right.

Value

value. Thus one can use \( \text{a <-b <-c <-6} \).

References

See Also

\texttt{assign} (and its inverse \texttt{get}), for “subassignment” such as \( \text{x[i]} \) \(<-v\), see \texttt{[<-}; further, \texttt{environment}.

Description

The database is attached to the \( \text{R} \) search path. This means that the database is searched by \( \text{R} \) when evaluating a variable, so objects in the database can be accessed by simply giving their names.

Usage

\texttt{attach(what, pos = 2L, name = deparse1(substitute(what), backtick=FALSE), warn.conflicts = TRUE)}
Arguments

what ‘database’. This can be a data.frame or a list or a R data file created with save or NULL or an environment. See also ‘Details’.
pos integer specifying position in search() where to attach.
name name to use for the attached database. Names starting with package: are reserved for library.
warn.conflicts logical. If TRUE, warnings are printed about conflicts from attaching the database, unless that database contains an object .conflicts.OK. A conflict is a function masking a function, or a non-function masking a non-function.

Details

When evaluating a variable or function name R searches for that name in the databases listed by search. The first name of the appropriate type is used.

By attaching a data frame (or list) to the search path it is possible to refer to the variables in the data frame by their names alone, rather than as components of the data frame (e.g., in the example below, height rather than women$height).

By default the database is attached in position 2 in the search path, immediately after the user’s workspace and before all previously attached packages and previously attached databases. This can be altered to attach later in the search path with the pos option, but you cannot attach at pos = 1.

The database is not actually attached. Rather, a new environment is created on the search path and the elements of a list (including columns of a data frame) or objects in a save file or an environment are copied into the new environment. If you use <<- or assign to assign to an attached database, you only alter the attached copy, not the original object. (Normal assignment will place a modified version in the user’s workspace: see the examples.) For this reason attach can lead to confusion.

One useful ‘trick’ is to use what = NULL (or equivalently a length-zero list) to create a new environment on the search path into which objects can be assigned by assign or load or sys.source.

Names starting ”package:" are reserved for library and should not be used by end users. Attached files are by default given the name file:what. The name argument given for the attached environment will be used by search and can be used as the argument to as.environment.

There are hooks to attach user-defined table objects of class ”UserDefinedDatabase”, supported by the Omegahat package RObjectTables.

Value

The environment is returned invisibly with a ”name” attribute.

Good practice

attach has the side effect of altering the search path and this can easily lead to the wrong object of a particular name being found. People do often forget to detach databases.

In interactive use, with is usually preferable to the use of attach/detach, unless what is a save()-produced file in which case attach() is a (safety) wrapper for load().

In programming, functions should not change the search path unless that is their purpose. Often with can be used within a function. If not, good practice is to

• Always use a distinctive name argument, and

• To immediately follow the attach call by an on.exit call to detach using the distinctive name.
This ensures that the search path is left unchanged even if the function is interrupted or if code after the `attach` call changes the search path.

### References

`library, detach, search, objects, environment, with`.

### Examples

```r
require(utils)

summary(women$height) # refers to variable 'height' in the data frame
attach(women)
summary(height)       # The same variable now available by name
height <- height*2.54  # Don't do this. It creates a new variable
                      # in the user's workspace
find("height")
summary(height)       # The new variable in the workspace
rm(height)
summary(height)       # The original variable.
height <<- height*25.4 # Change the copy in the attached environment
find("height")
summary(height)       # The changed copy
detach("women")
summary(women$height) # unchanged

## Not run: ## create an environment on the search path and populate it
sys.source("myfuns.R", envir = attach(NULL, name = "myfuns"))

## End(Not run)
```

---

**attr**

### Object Attributes

Get or set specific attributes of an object.

### Usage

```r
attr(x, which, exact = FALSE)
attr(x, which) <- value
```

### Arguments

- **x**: an object whose attributes are to be accessed.
- **which**: a non-empty character string specifying which attribute is to be accessed.
- **exact**: logical: should which be matched exactly?
- **value**: an object, the new value of the attribute, or NULL to remove the attribute.
Details

These functions provide access to a single attribute of an object. The replacement form causes the named attribute to take the value specified (or create a new attribute with the value given).

The extraction function first looks for an exact match to which amongst the attributes of x, then (unless exact = TRUE) a unique partial match. (Setting options(warnPartialMatchAttr = TRUE) causes partial matches to give warnings.)

The replacement function only uses exact matches.

Note that some attributes (namely class, comment, dim, dimnames, names, row.names and tsp) are treated specially and have restrictions on the values which can be set. (Note that this is not true of levels which should be set for factors via the levels replacement function.)

The extractor function allows (and does not match) empty and missing values of which: the replacement function does not.

NULL objects cannot have attributes and attempting to assign one by attr gives an error.

Both are primitive functions.

Value

For the extractor, the value of the attribute matched, or NULL if no exact match is found and no or more than one partial match is found.

References

See Also

attributes

Examples

# create a 2 by 5 matrix
x <- 1:10
attr(x,"dim") <- c(2, 5)

attributes(x)  
Object Attribute Lists

Description

These functions access an object’s attributes. The first form below returns the object’s attribute list. The replacement forms uses the list on the right-hand side of the assignment as the object’s attributes (if appropriate).

Usage

attributes(x)
attributes(x) <- value
mostattributes(x) <- value
Arguments

\( x \)

any \( R \) object

value

an appropriate named \textbf{list} of attributes, or \texttt{NULL}.

Details

Unlike \texttt{attr} it is not an error to set attributes on a \texttt{NULL} object: it will first be coerced to an empty list.

Note that some attributes (namely \texttt{class}, \texttt{comment}, \texttt{dim}, \texttt{dimnames}, \texttt{names}, \texttt{row.names} and \texttt{tsp}) are treated specially and have restrictions on the values which can be set. (Note that this is not true of \texttt{levels} which should be set for factors via the \texttt{levels} replacement function.) Attributes are not stored internally as a list and should be thought of as a set and not a vector, i.e., the order of the elements of \texttt{attributes()} does not matter. This is also reflected by \texttt{identical()}'s behaviour with the default argument \texttt{attrib.as.set = TRUE}. Attributes must have unique names (and \texttt{NA} is taken as "NA", not a missing value).

Assigning attributes first removes all attributes, then sets any \texttt{dim} attribute and then the remaining attributes in the order given: this ensures that setting a \texttt{dim} attribute always precedes the \texttt{dimnames} attribute.

The mostattributes assignment takes special care for the \texttt{dim}, \texttt{names} and \texttt{dimnames} attributes, and assigns them only when known to be valid whereas an attributes assignment would give an error if any are not. It is principally intended for arrays, and should be used with care on classed objects. For example, it does not check that \texttt{row.names} are assigned correctly for data frames.

The names of a pairlist are not stored as attributes, but are reported as if they were (and can be set by the replacement form of \texttt{attributes}).

\texttt{NULL} objects cannot have attributes and attempts to assign them will promote the object to an empty list.

Both assignment and replacement forms of \texttt{attributes} are \texttt{primitive} functions.

Examples

\begin{verbatim}
x <- cbind(a = 1:3, pi = pi) # simple matrix with dimnames
attributes(x)

## strip an object's attributes:
attributes(x) <- NULL
x # now just a vector of length 6

mostattributes(x) <- list(mycomment = "really special", dim = 3:2,
                         dimnames = list(LETTERS[1:3], letters[1:5]), names = paste(1:6))
x # dim(), but not (dim)names
\end{verbatim}
autoload

On-demand Loading of Packages

Description

autoload creates a promise-to-evaluate autoloader and stores it with name name in .AutoloadEnv environment. When R attempts to evaluate name, autoloader is run, the package is loaded and name is re-evaluated in the new package’s environment. The result is that R behaves as if package was loaded but it does not occupy memory.

.autoloaded contains the names of the packages for which autoloading has been promised.

Usage

autoload(name, package, reset = FALSE, ...)
autoloader(name, package, ...)

*.AutoloadEnv
*.Autoloaded

Arguments

name string giving the name of an object.
package string giving the name of a package containing the object.
reset logical: for internal use by autoloader.
... other arguments to library.

Value

This function is invoked for its side-effect. It has no return value.

See Also

delayedAssign, library

Examples

require(stats)
autoload("interpSpline", "splines")
search()
ls("Autoloads")
.Autoloaded

x <- sort(stats::rnorm(12))
y <- x^2
is <- interpSpline(x, y)
search() # now has splines
detach("package:splines")
search() is2 <- interpSpline(x, y+x)
search() # and again
detach("package:splines")
backsolve

Solve an Upper or Lower Triangular System

Description

Solves a triangular system of linear equations.

Usage

backsolve(r, x, k = ncol(r), upper.tri = TRUE, transpose = FALSE)
forwardsolve(l, x, k = ncol(l), upper.tri = FALSE, transpose = FALSE)

Arguments

r, l
an upper (or lower) triangular matrix giving the coefficients for the system to be solved. Values below (above) the diagonal are ignored.
x
a matrix whose columns give the right-hand sides for the equations.
k
The number of columns of r and rows of x to use.
upper.tri
logical; if TRUE (default), the upper triangular part of r is used. Otherwise, the lower one.
transpose
logical; if TRUE, solve r′ * y = x for y, i.e., t(r) %*% y == x.

Details

Solves a system of linear equations where the coefficient matrix is upper (or ‘right’, ‘R’) or lower (‘left’, ‘L’) triangular.

x <- backsolve (R, b) solves Rx = b, and
x <- forwardsolve(L, b) solves Lx = b, respectively.

The r/l must have at least k rows and columns, and x must have at least k rows.

This is a wrapper for the level-3 BLAS routine dtrsm.

Value

The solution of the triangular system. The result will be a vector if x is a vector and a matrix if x is a matrix.

chol, qr, solve.
Examples

## upper triangular matrix 'r':
```
r <- rbind(c(1,2,3),
           c(0,1,1),
           c(0,0,2))
(y <- backsolve(r, x <- c(8,4,2)) ) # -1 3 1
r %*% y # == x = (8,4,2)
```

```
backsolve(r, x, transpose = TRUE) # 8 -12 -5
```

## Manipulate File Paths

### Description

basename removes all of the path up to and including the last path separator (if any). dirname returns the part of the path up to but excluding the last path separator, or "." if there is no path separator.

### Usage

```
basename(path)
dirname(path)
```

### Arguments

- **path** character vector, containing path names.

### Details

- **tilde expansion** of the path is done except on Windows.
- Trailing path separators are removed before dissecting the path, and for dirname any trailing file separators are removed from the result.

### Value

A character vector of the same length as path. A zero-length input will give a zero-length output with no error.

- Paths not containing any separators are taken to be in the current directory, so dirname returns ".".
- If an element of path is NA, so is the result.
- "" is not a valid pathname, but is returned unchanged.

### Behaviour on Windows

On Windows this will accept either \ or / as the path separator, but dirname will return a path using / (except if on a network share, when the leading \ will be preserved). Expect these only to be able to handle complete paths, and not for example just a network share or a drive.

UTF-8-encoded path names not valid in the current locale can be used.
Note

These are not wrappers for the POSIX system functions of the same names: in particular they do not have the special handling of the path "/" and of returning "." for empty strings.

See Also

file.path, path.expand.

Examples

basename(file.path("","p1","p2","p3", c("file1", "file2")))
dirname(file.path("","p1","p2","p3","filename"))

Bessel Functions

Description

Bessel Functions of integer and fractional order, of first and second kind, \( J_\nu \) and \( Y_\nu \), and Modified Bessel functions (of first and third kind), \( I_\nu \) and \( K_\nu \).

Usage

besselI(x, nu, expon.scaled = FALSE)
besselK(x, nu, expon.scaled = FALSE)
besselJ(x, nu)
besselY(x, nu)

Arguments

x numeric, \( \geq 0 \).
nu numeric; The order (maybe fractional and negative) of the corresponding Bessel function.
expon.scaled logical; if TRUE, the results are exponentially scaled in order to avoid overflow \( (I_\nu) \) or underflow \( (K_\nu) \), respectively.

Details

If expon.scaled = TRUE, \( e^{-x}I_\nu(x) \) or \( e^xK_\nu(x) \) are returned.

For \( \nu < 0 \), formulae 9.1.2 and 9.6.2 from Abramowitz & Stegun are applied (which is probably suboptimal), except for besselK which is symmetric in nu.

The current algorithms will give warnings about accuracy loss for large arguments. In some cases, these warnings are exaggerated, and the precision is perfect. For large nu, say in the order of millions, the current algorithms are rarely useful.

Value

Numeric vector with the (scaled, if expon.scaled = TRUE) values of the corresponding Bessel function.

The length of the result is the maximum of the lengths of the parameters. All parameters are recycled to that length.
Bessel

### Description

These functions represent an interface for adjustments to environments and bindings within environments. They allow for locking environments as well as individual bindings, and for linking a variable to a function.

### Usage

```r
lockEnvironment(env, bindings = FALSE)
environmentIsLocked(env)
lockBinding(sym, env)
unlockBinding(sym, env)
bindingIsLocked(sym, env)

makeActiveBinding(sym, fun, env)
bindingIsActive(sym, env)
activeBindingFunction(sym, env)
```

### Arguments

- `env` an environment.
- `bindings` logical specifying whether bindings should be locked.
- `sym` a name object or character string.
- `fun` a function taking zero or one arguments.

### Details

The function `lockEnvironment` locks its environment argument, which must be a normal environment (not base). (Locking the base environment and namespace may be supported later.) Locking the environment prevents adding or removing variable bindings from the environment. Changing the value of a variable is still possible unless the binding has been locked. The namespace environments of packages with namespaces are locked when loaded.

`lockBinding` locks individual bindings in the specified environment. The value of a locked binding cannot be changed. Locked bindings may be removed from an environment unless the environment is locked.
makeActiveBinding installs fun in environment env so that getting the value of sym calls fun with no arguments, and assigning to sym calls fun with one argument, the value to be assigned. This allows the implementation of things like C variables linked to R variables and variables linked to databases, and is used to implement setRefClass. It may also be useful for making thread-safe versions of some system globals. Currently active bindings are not preserved during package installation, but they can be created in .onLoad.

Value

The bindingIsLocked and environmentIsLocked return a length-one logical vector. The remaining functions return NULL, invisibly.

Author(s)

Luke Tierney

Examples

# locking environments
e <- new.env()
assign("x", 1, envir = e)
get("x", envir = e)
lockEnvironment(e)
get("x", envir = e)
assign("x", 2, envir = e)
try(assign("y", 2, envir = e)) # error

# locking bindings
e <- new.env()
assign("x", 1, envir = e)
get("x", envir = e)
lockBinding("x", e)
try(assign("x", 2, envir = e)) # error
unlockBinding("x", e)
assign("x", 2, envir = e)
get("x", envir = e)

# active bindings
f <- local(
  x <- 1
  function(v) {
    if (missing(v))
      cat("get\n")
    else {
      cat("set\n")
      x <<- v
    }
  }
  x
)
makeActiveBinding("fred", f, .GlobalEnv)
bindingIsActive("fred", .GlobalEnv)
fred
fred <- 2
fred
**Description**

Logical operations on integer vectors with elements viewed as sets of bits.

**Usage**

- `bitwNot(a)`
- `bitwAnd(a, b)`
- `bitwOr(a, b)`
- `bitwXor(a, b)`
- `bitwShiftL(a, n)`
- `bitwShiftR(a, n)`

**Arguments**

- `a, b` integer vectors; numeric vectors are coerced to integer vectors.
- `n` non-negative integer vector of values up to 31.

**Details**

- Each element of an integer vector has 32 bits.
- Pairwise operations can result in integer `NA`.
- Shifting is done assuming the values represent unsigned integers.

**Value**

An integer vector of length the longer of the arguments, or zero length if one is zero-length.

The output element is `NA` if an input is `NA` (after coercion) or an invalid shift.

**See Also**

The logical operators, `!`, `&`, `|`, `xor`. Notably these do work bitwise for `raw` arguments.

The classes "octmode" and "hexmode" whose implementation of the standard logical operators is based on these functions.

Package `bitops` has similar functions for numeric vectors which differ in the way they treat integers $2^{31}$ or larger.

**Examples**

```
bitwNot(0:12) # -1 -2 ... -13
bitwAnd(15L, 7L) # 7
bitwOr(15L, 7L) # 15
bitwXor(15L, 7L) # 8
bitwXor(-1L, 1L) # -2
```

```r
## The "same" for 'raw' instead of integer :
```
body <- as.raw(0:12) ; rbind(body, !body)

c(r15 <- as.raw(15), r7 <- as.raw(7)) # 0f 07
r15 & r7 # 07
r15 | r7 # 0f
xor(r15, r7)# 08

bitwShiftR(-1, 1:31) # shifts of 2^32-1 = 4294967295

--

body

Access to and Manipulation of the Body of a Function

Description

Get or set the body of a function which is basically all of the function definition but its formal arguments (formals), see the ‘Details’.

Usage

body(fun = sys.function(sys.parent()))
body(fun, envir = environment(fun)) <- value

Arguments

fun a function object, or see ‘Details’.
envir environment in which the function should be defined.
value an object, usually a language object: see section ‘Value’.

Details

For the first form, fun can be a character string naming the function to be manipulated, which is searched for from the parent frame. If it is not specified, the function calling body is used.

The bodies of all but the simplest are braced expressions, that is calls to {: see the ‘Examples’ section for how to create such a call.

Value

body returns the body of the function specified. This is normally a language object, most often a call to {, but it can also be a symbol such as pi or a constant (e.g., 3 or "R") to be the return value of the function.

The replacement form sets the body of a function to the object on the right hand side, and (potentially) resets the environment of the function, and drops attributes. If value is of class "expression" the first element is used as the body: any additional elements are ignored, with a warning.

See Also

The three parts of a (non-primitive) function are its formals, body, and environment.

Further, see alist, args, function.
Examples

body(body)
f <- function(x) x^5
body(f) <- quote(5^x)
## or equivalently body(f) <- expression(5^x)
f(3) # = 125
body(f)

## creating a multi-expression body
e <- expression(y <- x^2, return(y)) # or a list
body(f) <- as.call(c(as.name("\{"), e))
f
f(8)

## Using substitute() may be simpler than 'as.call(c(as.name("\{","\}))(y <- x^2; return(y)))':
stopifnot(identical(body(f), substitute({ y <- x^2; return(y) })))

bquote

Partial substitution in expressions

Description

An analogue of the LISP backquote macro. bquote quotes its argument except that terms wrapped in .() are evaluated in the specified where environment. If splice = TRUE then terms wrapped in ..() are evaluated and spliced into a call.

Usage

bquote(expr, where = parent.frame(), splice = FALSE)

Arguments

expr A language object.
where An environment.
splice Logical; if TRUE splicing is enabled.

Value

A language object.

See Also

quote, substitute

Examples

require(graphics)
a <- 2
bquote(a == a)
quote(a == a)
bquote(a == .(a))
substitute(a == A, list(A = a))

plot(1:10, a*(1:10), main = bquote(a == .(a)))

## to set a function default arg
default <- 1
bquote( function(x, y = .(default)) x+y )

eprs <- expression(x <- 1, y <- 2, x + y)
bquote(function() {..(exprs)}, splice = TRUE)

---

### browser

**Environment Browser**

#### Description

Interrupt the execution of an expression and allow the inspection of the environment where browser was called from.

#### Usage

```r
browser(text = "", condition = NULL, expr = TRUE, skipCalls = 0L)
```

#### Arguments

- **text**: a text string that can be retrieved once the browser is invoked.
- **condition**: a condition that can be retrieved once the browser is invoked.
- **expr**: An expression, which if it evaluates to TRUE the debugger will invoked, otherwise control is returned directly.
- **skipCalls**: how many previous calls to skip when reporting the calling context.

#### Details

A call to browser can be included in the body of a function. When reached, this causes a pause in the execution of the current expression and allows access to the R interpreter.

The purpose of the text and condition arguments are to allow helper programs (e.g., external debuggers) to insert specific values here, so that the specific call to browser (perhaps its location in a source file) can be identified and special processing can be achieved. The values can be retrieved by calling `browserText` and `browserCondition`.

The purpose of the expr argument is to allow for the illusion of conditional debugging. It is an illusion, because execution is always paused at the call to browser, but control is only passed to the evaluator described below if expr evaluates to TRUE. In most cases it is going to be more efficient to use an if statement in the calling program, but in some cases using this argument will be simpler.

The skipCalls argument should be used when the browser() call is nested within another debugging function: it will look further up the call stack to report its location.

At the browser prompt the user can enter commands or R expressions, followed by a newline. The commands are

- c  exit the browser and continue execution at the next statement.
cont synonym for c.

f finish execution of the current loop or function

help print this list of commands

n evaluate the next statement, stepping over function calls. For byte compiled functions interrupted by browser calls, n is equivalent to c.

s evaluate the next statement, stepping into function calls. Again, byte compiled functions make s equivalent to c.

where print a stack trace of all active function calls.

r invoke a "resume" restart if one is available; interpreted as an R expression otherwise. Typically "resume" restarts are established for continuing from user interrupts.

Q exit the browser and the current evaluation and return to the top-level prompt.

Leading and trailing whitespace is ignored, except for an empty line. Handling of empty lines depends on the "browserNLdisabled" option; if it is TRUE, empty lines are ignored. If not, an empty line is the same as n (or s, if it was used most recently).

Anything else entered at the browser prompt is interpreted as an R expression to be evaluated in the calling environment: in particular typing an object name will cause the object to be printed, and ls() lists the objects in the calling frame. (If you want to look at an object with a name such as n, print it explicitly, or use autoprint via (n).

The number of lines printed for the deparsed call can be limited by setting options(deparse.max.lines).

The browser prompt is of the form Browse[n]>: here var{n} indicates the ‘browser level’. The browser can be called when browsing (and often is when debug is in use), and each recursive call increases the number. (The actual number is the number of ‘contexts’ on the context stack: this is usually 2 for the outer level of browsing and 1 when examining dumps in debugger.)

This is a primitive function but does argument matching in the standard way.

References

See Also
debug, and traceback for the stack on error. browserText for how to retrieve the text and condition.
Usage

browserText(n = 1)
browserCondition(n = 1)
browserSetDebug(n = 1)

Arguments

n  The number of contexts to skip over, it must be non-negative.

Details

Each call to browser can supply either a text string or a condition. The functions browserText and browserCondition provide ways to retrieve those values. Since there can be multiple browser contexts active at any time we also support retrieving values from the different contexts. The innermost (most recently initiated) browser context is numbered 1: other contexts are numbered sequentially.

browserSetDebug provides a mechanism for initiating the browser in one of the calling functions. See sys.frame for a more complete discussion of the calling stack. To use browserSetDebug you select some calling function, determine how far back it is in the call stack and call browserSetDebug with n set to that value. Then, by typing c at the browser prompt you will cause evaluation to continue, and provided there are no intervening calls to browser or other interrupts, control will halt again once evaluation has returned to the closure specified. This is similar to the up functionality in gdb or the "step out" functionality in other debuggers.

Value

browserText returns the text, while browserCondition returns the condition from the specified browser context.
browserSetDebug returns NULL, invisibly.

Note

It may be of interest to allow for querying further up the set of browser contexts and this functionality may be added at a later date.

browser

Returns the Names of All Built-in Objects

Description

Return the names of all the built-in objects. These are fetched directly from the symbol table of the R interpreter.
Usage

```r
builtins(internal = FALSE)
```

Arguments

- `internal` a logical indicating whether only ‘internal’ functions (which can be called via `.Internal`) should be returned.

Details

- `builtins()` returns an unsorted list of the objects in the symbol table, that is all the objects in the base environment. These are the built-in objects plus any that have been added subsequently when the base package was loaded. It is less confusing to use `ls(baseenv(), all = TRUE)`.
- `builtins(TRUE)` returns an unsorted list of the names of internal functions, that is those which can be accessed as `.Internal(foo(args ...))` for `foo` in the list.

Value

A character vector.

---

by

**Apply a Function to a Data Frame Split by Factors**

Description

Function `by` is an object-oriented wrapper for `tapply` applied to data frames.

Usage

```r
by(data, INDICES, FUN, ..., simplify = TRUE)
```

Arguments

- `data` an R object, normally a data frame, possibly a matrix.
- `INDICES` a factor or a list of factors, each of length `nrow(data)`.
- `FUN` a function to be applied to (usually data-frame) subsets of data.
- `...` further arguments to `FUN`.
- `simplify` logical: see `tapply`.

Details

A data frame is split by row into data frames subsetted by the values of one or more factors, and function `FUN` is applied to each subset in turn.

For the default method, an object with dimensions (e.g., a matrix) is coerced to a data frame and the data frame method applied. Other objects are also coerced to a data frame, but `FUN` is applied separately to (subsets of) each column of the data frame.

Value

An object of class "by", giving the results for each subset. This is always a list if `simplify` is false, otherwise a list or array (see `tapply`).
c

Combine Values into a Vector or List

Description

This is a generic function which combines its arguments. The default method combines its arguments to form a vector. All arguments are coerced to a common type which is the type of the returned value, and all attributes except names are removed.

Usage

## S3 Generic function

\texttt{c(...)}

## Default S3 method:

\texttt{c(..., recursive = FALSE, use.names = TRUE)}

Arguments

\texttt{...} objects to be concatenated. All \texttt{NULL} entries are dropped before method dispatch unless at the very beginning of the argument list.

\texttt{recursive} logical. If \texttt{recursive = TRUE}, the function recursively descends through lists (and pairlists) combining all their elements into a vector.

\texttt{use.names} logical indicating if \texttt{names} should be preserved.

Details

The output type is determined from the highest type of the components in the hierarchy \texttt{NULL} < \texttt{raw} < \texttt{logical} < \texttt{integer} < \texttt{double} < \texttt{complex} < \texttt{character} < \texttt{list} < \texttt{expression}. Pairlists are treated as lists, whereas non-vector components (such as \texttt{names} / symbols and \texttt{calls}) are treated as one-element lists which cannot be unlisted even if \texttt{recursive = TRUE}.

Note that in R < 4.1.0, \texttt{factors} were treated only via their internal \texttt{integer} codes: now there is \texttt{c.factor} method which combines factors into a factor.

Examples

\begin{verbatim}
require(stats)
by(warpbreaks[, 1:2], warpbreaks[, "tension"], summary)
by(warpbreaks[, 1], warpbreaks[, -1], summary)
by(warpbreaks, warpbreaks[, "tension"],
  function(x) lm(breaks ~ wool, data = x))

## now suppose we want to extract the coefficients by group
tmp <- with(warpbreaks,
  by(warpbreaks, tension,
    function(x) lm(breaks ~ wool, data = x)))

sapply(tmp, coef)
\end{verbatim}
c is sometimes used for its side effect of removing attributes except names, for example to turn an array into a vector. `as.vector` is a more intuitive way to do this, but also drops names. Note that methods other than the default are not required to do this (and they will almost certainly preserve a class attribute).

This is a primitive function.

**Value**

NULL or an expression or a vector of an appropriate mode. (With no arguments the value is NULL.)

**S4 methods**

This function is S4 generic, but with argument list `(x, ...)`.

**References**

**See Also**

`unlist` and `as.vector` to produce attribute-free vectors.

**Examples**

c(1,7:9)
c(1:5, 10.5, "next")

## uses with a single argument to drop attributes
x <- 1:4
names(x) <- letters[1:4]
x
c(x)  # has names
as.vector(x)  # no names
dim(x) <- c(2,2)
x
c(x)
as.vector(x)

## append to a list:
ll <- list(A = 1, c = "C")
## do *not* use
c(ll, d = 1:3)  # which is == c(ll, as.list(c(d = 1:3))))
## but rather
c(ll, d = list(1:3))  # c() combining two lists

c(list(A = c(B = 1)), recursive = TRUE)
c(options(), recursive = TRUE)
c(list(A = c(B = 1, C = 2), B = c(E = 7)), recursive = TRUE)
Description

Create or test for objects of mode "call" (or "()", see Details).

Usage

call(name, ...)  
is.call(x)  
as.call(x)

Arguments

name  a non-empty character string naming the function to be called.  
...  arguments to be part of the call.  
x  an arbitrary R object.

Details

call returns an unevaluated function call, that is, an unevaluated expression which consists of the named function applied to the given arguments (name must be a quoted string which gives the name of a function to be called). Note that although the call is unevaluated, the arguments ... are evaluated.

call is a primitive, so the first argument is taken as name and the remaining arguments as arguments for the constructed call: if the first argument is named the name must partially match name.

is.call is used to determine whether x is a call (i.e., of mode "call" or "()"). Note that

• is.call(x) is strictly equivalent to typeof(x) == "language".
• is.language() is also true for calls (but also for symbols and expressions where is.call() is false).

as.call(x): Objects of mode "list" can be coerced to mode "call". The first element of the list becomes the function part of the call, so should be a function or the name of one (as a symbol; a quoted string will not do).

If you think of using as.call(<string>), consider using str2lang(*) which is an efficient version of parse(text=*) . Note that call() and as.call(), when applicable, are much preferable to these parse() based approaches.

All three are primitive functions.

as.call is generic: you can write methods to handle specific classes of objects, see InternalMethods.

Warning

call should not be used to attempt to evade restrictions on the use of .Internal and other non-API calls.
callCC

References

See Also
do.call for calling a function by name and argument list; Recall for recursive calling of functions; further is.language, expression, function.
Producing calls etc from character: str2lang and parse.

Examples

is.call(call) #-> FALSE: Functions are NOT calls

### set up a function call to round with argument 10.5
c1 <- call("round", 10.5)
is.call(c1) # TRUE
c1
identical(quote(round(10.5)), # <- less functional, but the same
c1) # TRUE

### such a call can also be evaluated.
eval(c1) # [1] 10

class(c1) # "call"
typeof(c1)# "language"
is.call(c1) && is.language(c1) # always TRUE for "call"s

A <- 10.5
call("round", A) # round(10.5)
call("round", quote(A)) # round(A)
f <- "round"
call(f, quote(A)) # round(A)

### if we want to supply a function we need to use as.call or similar
f <- round

### Not run: call(f, quote(A)) # error: first arg must be character
(g <- as.call(list(f, quote(A))))
eval(g)

### alternatively but less transparently
(g <- list(f, quote(A)))
mode(g) <- "call"
g
eval(g)

### see also the examples in the help for do.call

callCC

Call With Current Continuation

Description
A downward-only version of Scheme’s call with current continuation.

Usage
callCC(fun)
Arguments

fun function of one argument, the exit procedure.

Details

callCC provides a non-local exit mechanism that can be useful for early termination of a computation. callCC calls fun with one argument, an exit function. The exit function takes a single argument, the intended return value. If the body of fun calls the exit function then the call to callCC immediately returns, with the value supplied to the exit function as the value returned by callCC.

Author(s)

Luke Tierney

Examples

# The following all return the value 1
callCC(function(k) 1)
callCC(function(k) k(1))
callCC(function(k) (k(1); 2))
callCC(function(k) repeat k(1))

data.frame(1:10, .Call("sum", 1:10))

CallExternal Modern Interfaces to C/C++ code

Description

Functions to pass R objects to compiled C/C++ code that has been loaded into R.

Usage

.Call(.NAME, ..., PACKAGE)
.External(.NAME, ..., PACKAGE)

Arguments

.NAME a character string giving the name of a C function, or an object of class "NativeSymbolInfo", "RegisteredNativeSymbol" or "NativeSymbol" referring to such a name.

... arguments to be passed to the compiled code. Up to 65 for .Call.

PACKAGE if supplied, confine the search for a character string .NAME to the DLL given by this argument (plus the conventional extension, ’.so’, ’.dll’, ...). This argument follows ... and so its name cannot be abbreviated. This is intended to add safety for packages, which can ensure by using this argument that no other package can override their external symbols, and also speeds up the search (see ’Note’).
The functions are used to call compiled code which makes use of internal R objects, passing the arguments to the code as a sequence of R objects. They assume C calling conventions, so can usually also be used for C++ code.

For details about how to write code to use with these functions see the chapter on 'System and foreign language interfaces' in the 'Writing R Extensions' manual. They differ in the way the arguments are passed to the C code: .External allows for a variable or unlimited number of arguments.

These functions are primitive, and .NAME is always matched to the first argument supplied (which should not be named). For clarity, avoid using names in the arguments passed to .NAME that match or partially match .NAME.

Value
An R object constructed in the compiled code.

Header files for external code
Writing code for use with these functions will need to use internal R structures defined in 'Rinternals.h' and/or the macros in 'Rdefines.h'.

Note
If one of these functions is to be used frequently, do specify PACKAGE (to confine the search to a single DLL) or pass .NAME as one of the native symbol objects. Searching for symbols can take a long time, especially when many namespaces are loaded.

You may see PACKAGE = "base" for symbols linked into R. Do not use this in your own code: such symbols are not part of the API and may be changed without warning. PACKAGE = "" used to be accepted (but was undocumented): it is now an error.

Report Capabilities of this Build of R

Report on the optional features which have been compiled into this build of R.

capabilities

Report Capabilities of this Build of R

Usage
capabilities(what = NULL, Xchk = any(nas %in% c("X11", "jpeg", "png", "tiff")))
## Arguments

**what** character vector or NULL, specifying required components. NULL implies that all are required.

**Xchk** logical with a smart default, indicating if X11-related capabilities should be fully checked, notably on macOS. If set to false, may avoid a warning “No protocol specified” and e.g., the "X11" capability may be returned as NA.

## Value

A named logical vector. Current components are

- jpeg is the jpeg function operational?
- png is the png function operational?
- tiff is the tiff function operational?
- tcltk is the tcltk package operational? Note that to make use of Tk you will almost always need to check that "X11" is also available.
- X11 are the X11 graphics device and the X11-based data editor available? This loads the X11 module if not already loaded, and checks that the default display can be contacted unless a X11 device has already been used.
- aqua is the quartz function operational? Only on some macOS builds, including CRAN binary distributions of R. Note that this is distinct from .Platform$GUI == "AQUA", which is true only when using the Mac R.app GUI console.
- http/ftp does the internal method for url and download.file support ‘http://’ and ‘ftp://’ URLs? Always TRUE as from R 3.3.0.
- sockets are make.socket and related functions available? Always TRUE as from R 3.3.0.
- libxml is there support for integrating libxml with the R event loop? Always TRUE as from R 3.3.0.
- fifo are FIFO connections supported?
- cledit is command-line editing available in the current R session? This is false in non-interactive sessions. It will be true for the command-line interface if readline support has been compiled in and ‘--no-readline’ was not used when R was invoked. (If ‘--interactive’ was used, command-line editing will not actually be available.)
- iconv is internationalization conversion via iconv supported? Always true in current R.
- NLS is there Natural Language Support (for message translations)?
- Rprof is there support for Rprof() profiling? This is true if R was configured (before compilation) with default settings which include --enable-R-profiling.
- profmem is there support for memory profiling? See tracemem.
- cairo is there support for the svg, cairo_pdf and cairo_ps devices, and for type = "cairo" in the X11, bmp, jpeg, png, and tiff devices?
- ICU is ICU available for collation? See the help on Comparison and icuSetCollate: it is never used for a C locale.
long.double does this build use a C long double type which is longer than double? Some platforms do not have such a type, and on others its use can be suppressed by the configure option ‘--disable-long-double’.

Although not guaranteed, it is a reasonable assumption that if present long doubles will have at least as much range and accuracy as the ISO/IEC 60559 80-bit 'extended precision' format.

libcurl is libcurl available in this build? Used by function curlGetHeaders and optionally by download.file and url. As from R 3.3.0 always true for Unix-alikes, and true for CRAN Windows builds.

Note to macOS users

Capabilities "jpeg", "png" and "tiff" refer to the X11-based versions of these devices. If capabilities("aqua") is true, then these devices with type = "quartz" will be available, and out-of-the-box will be the default type. Thus for example the tiff device will be available if capabilities("aqua") || capabilities("tiff") if the defaults are unchanged.

See Also

.Platform and extSoftVersion (and links there) for availability capabilities external to R but used from R functions.

Examples

capabilities()

if(!capabilities("ICU"))
  warning("ICU is not available")

## Does not call the internal X11-checking function:
capabilities(Xchk = FALSE)

## See also the examples for 'connections'.

cat Concatenate and Print

Description

Outputs the objects, concatenating the representations. cat performs much less conversion than print.

Usage

cat(..., file = "", sep = " ", fill = FALSE, labels = NULL, append = FALSE)
Arguments

- **R objects** (see 'Details' for the types of objects allowed).
- **file** A connection, or a character string naming the file to print to. If "" (the default), `cat` prints to the standard output connection, the console unless redirected by `sink`. If it is "|cmd", the output is piped to the command given by `cmd`, by opening a pipe connection.
- **sep** A character vector of strings to append after each element.
- **fill** A logical or (positive) numeric controlling how the output is broken into successive lines. If FALSE (default), only newlines created explicitly by ‘\n’ are printed. Otherwise, the output is broken into lines with print width equal to the option width if fill is TRUE, or the value of fill if this is numeric. Linefeeds are only inserted between elements, strings wider than fill are not wrapped. Non-positive fill values are ignored, with a warning.
- **labels** Character vector of labels for the lines printed. Ignored if fill is FALSE.
- **append** Logical. Only used if the argument file is the name of file (and not a connection or "|cmd"). If TRUE output will be appended to file; otherwise, it will overwrite the contents of file.

Details

`cat` is useful for producing output in user-defined functions. It converts its arguments to character vectors, concatenates them to a single character vector, appends the given sep = string(s) to each element and then outputs them.

No linefeeds are output unless explicitly requested by ‘\n’ or if generated by filling (if argument fill is TRUE or numeric).

If file is a connection and open for writing it is written from its current position. If it is not open, it is opened for the duration of the call in "wt" mode and then closed again.

Currently only atomic vectors and names are handled, together with NULL and other zero-length objects (which produce no output). Character strings are output 'as is' (unlike `print.default` which escapes non-printable characters and backslash — use `encodeString` if you want to output encoded strings using `cat`). Other types of R object should be converted (e.g., by `as.character` or `format`) before being passed to `cat`. That includes factors, which are output as integer vectors.

`cat` converts numeric/complex elements in the same way as `print` (and not in the same way as `as.character` which is used by the S equivalent), so `options` "digits" and "scipen" are relevant. However, it uses the minimum field width necessary for each element, rather than the same field width for all elements.

Value

None (invisible NULL).

Note

If any element of sep contains a newline character, it is treated as a vector of terminators rather than separators, an element being output after every vector element and a newline after the last. Entries are recycled as needed.

References

cbind

Combine R Objects by Rows or Columns

Description

Take a sequence of vector, matrix or data-frame arguments and combine by columns or rows, respectively. These are generic functions with methods for other R classes.

Usage

```r
cbind(..., deparse.level = 1)
rbind(..., deparse.level = 1)
## S3 method for class 'data.frame'
rbind(..., deparse.level = 1, make.row.names = TRUE,
       stringsAsFactors = FALSE, factor.exclude = TRUE)
```

Arguments

- `...` (generalized) vectors or matrices. These can be given as named arguments. Other R objects may be coerced as appropriate, or S4 methods may be used: see sections ‘Details’ and ‘Value’. (For the "data.frame" method of cbind these can be further arguments to `data.frame` such as `stringsAsFactors`.)
- `deparse.level` integer controlling the construction of labels in the case of non-matrix-like arguments (for the default method):
deparse.level = 0 constructs no labels; the default,
deparse.level = 1 or 2 constructs labels from the argument names, see the ‘Value’ section below.
- `make.row.names` (only for data frame method:) logical indicating if unique and valid `row.names` should be constructed from the arguments.
- `stringsAsFactors` logical, passed to `as.data.frame`; only has an effect when the ... arguments contain a (non-data.frame) character.
- `factor.exclude` if the data frames contain factors, the default TRUE ensures that NA levels of factors are kept, see PR#17562 and the ‘Data frame methods’. In R versions up to 3.6.x, factor.exclude = NA has been implicitly hardcoded (R <= 3.6.0) or the default (R = 3.6.x, x >= 1).

See Also

`print`, `format`, and `paste` which concatenates into a string.

Examples

```r
iter <- stats::rpois(1, lambda = 10)
## print an informative message
cat("iteration = ", iter <- iter + 1, ",\n")
## 'fill' and label lines:
cat(paste(letters, 100* 1:26), fill = TRUE, labels = paste0("{", 1:10, ":\")
```

```r
```
Details

The functions `cbind` and `rbind` are S3 generic, with methods for data frames. The data frame method will be used if at least one argument is a data frame and the rest are vectors or matrices. There can be other methods; in particular, there is one for time series objects. See the section on ‘Dispatch’ for how the method to be used is selected. If some of the arguments are of an S4 class, i.e., `isS4(.)` is true, S4 methods are sought also, and the hidden `cbind` / `rbind` functions from package `methods` maybe called, which in turn build on `cbind2` or `rbind2`, respectively. In that case, `deparse.level` is obeyed, similarly to the default method.

In the default method, all the vectors/matrices must be atomic (see `vector`) or lists. Expressions are not allowed. Language objects (such as formulae and calls) and pairlists will be coerced to lists: other objects (such as names and external pointers) will be included as elements in a list result. Any classes the inputs might have have are discarded (in particular, factors are replaced by their internal codes).

If there are several matrix arguments, they must all have the same number of columns (or rows) and this will be the number of columns (or rows) of the result. If all the arguments are vectors, the number of columns (rows) in the result is equal to the length of the longest vector. Values in shorter arguments are recycled to achieve this length (with a warning if they are recycled only fractionally).

When the arguments consist of a mix of matrices and vectors the number of columns (rows) of the result is determined by the number of columns (rows) of the matrix arguments. Any vectors have their values recycled or subsetted to achieve this length.

For `cbind` (`rbind`), vectors of zero length (including `NULL`) are ignored unless the result would have zero rows (columns), for S compatibility. (Zero-extent matrices do not occur in S3 and are not ignored in R.)

Matrices are restricted to less than $2^{31}$ rows and columns even on 64-bit systems. So input vectors have the same length restriction: as from R 3.2.0 input matrices with more elements (but meeting the row and column restrictions) are allowed.

Value

For the default method, a matrix combining the ... arguments column-wise or row-wise. (Exception: if there are no inputs or all the inputs are `NULL`, the value is `NULL`.)

The type of a matrix result determined from the highest type of any of the inputs in the hierarchy `raw < logical < integer < double < complex < character < list`.

For `cbind` (`rbind`) the column (row) names are taken from the `colnames` (rownames) of the arguments if these are matrix-like. Otherwise from the names of the arguments or where those are not supplied and `deparse.level > 0`, by deparsing the expressions given, for `deparse.level = 1` only if that gives a sensible name (a ‘symbol’, see `is.symbol`).

For `cbind` row names are taken from the first argument with appropriate names: rownames for a matrix, or names for a vector of length the number of rows of the result.

For `rbind` column names are taken from the first argument with appropriate names: colnames for a matrix, or names for a vector of length the number of columns of the result.

Data frame methods

The `cbind` data frame method is just a wrapper for `data.frame(..., check.names = FALSE)`. This means that it will split matrix columns in data frame arguments, and convert character columns to factors unless `stringsAsFactors = FALSE` is specified.

The `rbind` data frame method first drops all zero-column and zero-row arguments. (If that leaves none, it returns the first argument with columns otherwise a zero-column zero-row data frame.)
It then takes the classes of the columns from the first data frame, and matches columns by name (rather than by position). Factors have their levels expanded as necessary (in the order of the levels of the level sets of the factors encountered) and the result is an ordered factor if and only if all the components were ordered factors. (The last point differs from S-PLUS.) Old-style categories (integer vectors with levels) are promoted to factors.

Note that for result column $j$, `factor(., exclude = X(j))` is applied, where

$$X(j) := \begin{cases} \text{if(isTRUE(factor.exclude))} & \{ \\
\text{if(!NA.lev[j]) NA # else NULL} \\
\text{else factor.exclude} & \}
\end{cases}$$

where $NA.lev[j]$ is true iff any contributing data frame has had a factor in column $j$ with an explicit NA level.

**Dispatch**

The method dispatching is *not* done via `UseMethod()`, but by C-internal dispatching. Therefore there is no need for, e.g., `rbind.default`.

The dispatch algorithm is described in the source file (`'.../src/main/bind.c'`) as

1. For each argument we get the list of possible class memberships from the class attribute.
2. We inspect each class in turn to see if there is an applicable method.
3. If we find a method, we use it. Otherwise, if there was an S4 object among the arguments, we try S4 dispatch; otherwise, we use the default code.

(Before R 4.0.0, an applicable method found was used only if identical to any method determined for prior arguments.)

If you want to combine other objects with data frames, it may be necessary to coerce them to data frames first. (Note that this algorithm can result in calling the data frame method if all the arguments are either data frames or vectors, and this will result in the coercion of character vectors to factors.)

**References**

**See Also**

c to combine vectors (and lists) as vectors, `data.frame` to combine vectors and matrices as a data frame.

**Examples**

```r
m <- cbind(1, 1:7) # the '1' (= shorter vector) is recycled
m
m <- cbind(m, 8:14)[, c(1, 3, 2)] # insert a column
m
cbind(1:7, diag(3)) # vector is subset -> warning

cbind(0, rbind(1, 1:3))
cbind(I = 0, X = rbind(a = 1, b = 1:3)) # use some names
xx <- data.frame(I = rep(0,2))
cbind(xx, X = rbind(a = 1, b = 1:3)) # named differently
```
char.expand

Expand a String with Respect to a Target Table

description

Seeks a unique match of its first argument among the elements of its second. If successful, it returns this element; otherwise, it performs an action specified by the third argument.

Usage

char.expand(input, target, nomatch = stop("no match"))

Arguments

input a character string to be expanded.
target a character vector with the values to be matched against.
nomatch an R expression to be evaluated in case expansion was not possible.

details

This function is particularly useful when abbreviations are allowed in function arguments, and need to be uniquely expanded with respect to a target table of possible values.

Value

A length-one character vector, one of the elements of target (unless nomatch is changed to be a non-error, when it can be a zero-length character string).

see also

charm match and pmatch for performing partial string matching.
Examples

locPars <- c("mean", "median", "mode")
char.expand("me", locPars, warning("Could not expand!"))
char.expand("mo", locPars)

Description

Create or test for objects of type "character".

Usage

character(length = 0)
as.character(x, ...)
is.character(x)

Arguments

length  A non-negative integer specifying the desired length. Double values will be coerced to integer: supplying an argument of length other than one is an error.
x     object to be coerced or tested.
...  further arguments passed to or from other methods.

Details

as.character and is.character are generic: you can write methods to handle specific classes of objects, see InternalMethods. Further, for as.character the default method calls as.vector, so dispatch is first on methods for as.character and then for methods for as.vector.
as.character represents real and complex numbers to 15 significant digits (technically the compiler’s setting of the ISO C constant DBL_DIG, which will be 15 on machines supporting IEC60559 arithmetic according to the C99 standard). This ensures that all the digits in the result will be reliable (and not the result of representation error), but does mean that conversion to character and back to numeric may change the number. If you want to convert numbers to character with the maximum possible precision, use format.

Value

character creates a character vector of the specified length. The elements of the vector are all equal to "".
as.character attempts to coerce its argument to character type; like as.vector it strips attributes including names. For lists and pairlists (including language objects such as calls) it deparses the elements individually, except that it extracts the first element of length-one character vectors.
is.character returns TRUE or FALSE depending on whether its argument is of character type or not.

Note

as.character breaks lines in language objects at 500 characters, and inserts newlines. Prior to 2.15.0 lines were truncated.
References

See Also

`options`: option `scipen` affects the conversion of numbers.

`paste`, `strsplit` and `strsplit` for character concatenation and splitting, `chartr` for character translation and casefolding (e.g., upper to lower case) and `sub`, `grep` etc for string matching and substitutions. Note that `help.search(keyword = "character")` gives even more links.

`deparse`, which is normally preferable to `as.character` for language objects.

Quotes on how to specify character / string constants, including `raw` ones.

Examples

```r
form <- y ~ a + b + c
as.character(form)  ## length 3
deparse(form)      ## like the input

a0 <- 11/999        # has a repeating decimal representation
(a1 <- as.character(a0))
format(a0, digits = 16) # shows one more digit
a2 <- as.numeric(a1)
a2 - a0             # normally around -1e-17
as.character(a2)    # normally different from a1
print(c(a0, a2), digits = 16)
```

---

**charmacth**  
*Partial String Matching*

Description

`charmacth` seeks matches for the elements of its first argument among those of its second.

Usage

`charmacth(x, table, nomatch = NA_integer_)`

Arguments

- **x**: the values to be matched: converted to a character vector by `as.character`. Long vectors are supported.
- **table**: the values to be matched against: converted to a character vector. Long vectors are not supported.
- **nomatch**: the (integer) value to be returned at non-matching positions.
chartr

Details

Exact matches are preferred to partial matches (those where the value to be matched has an exact match to the initial part of the target, but the target is longer).

If there is a single exact match or no exact match and a unique partial match then the index of the matching value is returned; if multiple exact or multiple partial matches are found then 0 is returned and if no match is found then nomatch is returned.

NA values are treated as the string constant "NA".

Value

An integer vector of the same length as x, giving the indices of the elements in table which matched, or nomatch.

Author(s)

This function is based on a C function written by Terry Therneau.

See Also

pmatch, match.

startsWith for another matching of initial parts of strings; grep or regexpr for more general (regexp) matching of strings.

Examples

charmatch("", ") # returns 1
charmatch("m", c("mean", "median", "mode")) # returns 0
charmatch("med", c("mean", "median", "mode")) # returns 2

chartr

Character Translation and Casefolding

Description

Translate characters in character vectors, in particular from upper to lower case or vice versa.

Usage

chartr(old, new, x)
tolower(x)
toupper(x)
casefold(x, upper = FALSE)

Arguments

x a character vector, or an object that can be coerced to character by as.character.
old a character string specifying the characters to be translated. If a character vector of length 2 or more is supplied, the first element is used with a warning.
new a character string specifying the translations. If a character vector of length 2 or more is supplied, the first element is used with a warning.
upper logical: translate to upper or lower case?
Details
chartr translates each character in x that is specified in old to the corresponding character specified
in new. Ranges are supported in the specifications, but character classes and repeated characters are
not. If old contains more characters than new, an error is signaled; if it contains fewer characters,
the extra characters at the end of new are ignored.
tolower and toupper convert upper-case characters in a character vector to lower-case, or vice
versa. Non-alphabetical characters are left unchanged.
casefold is a wrapper for tolower and toupper provided for compatibility with S-PLUS.

Value
A character vector of the same length and with the same attributes as x (after possible coercion).
Elements of the result will be have the encoding declared as that of the current locale (see Encoding)
if the corresponding input had a declared encoding and the current locale is either Latin-1 or UTF-
8. The result will be in the current locale’s encoding unless the corresponding input was in UTF-8,
when it will be in UTF-8 when the system has Unicode wide characters.

See Also
sub and gsub for other substitutions in strings.

Examples
x <- "MiXeD cAsE 123"
chartr("iXs", "why", x)
chartr("a-cX", "D-Fw", x)
tolower(x)
toupper(x)

## "Mixed Case" Capitalizing - toupper( every first letter of a word ) :

```r
.simpleCap <- function(x) {
  s <- strsplit(x, " ")[[1]]
  paste(toupper(substring(s, 1, 1)), substring(s, 2),
    sep = " ", collapse = " ")
}
.simpleCap("the quick red fox jumps over the lazy brown dog")
## -> [1] "The Quick Red Fox Jumps Over The Lazy Brown Dog"

## and the better, more sophisticated version:
capwords <- function(s, strict = FALSE) {
  cap <- function(s) paste(toupper(substring(s, 1, 1)),
    (s <- substring(s, 2); if(strict) tolower(s) else s),
    sep = " ", collapse = " ")
  sapply(strsplit(s, split = " "), cap, USE.NAMES = !is.null(names(s)))
}
capwords(c("using AIC for model selection"))
## -> [1] "Using AIC For Model Selection"
capwords(c("using AIC", "for MODEL selection"), strict = TRUE)
## -> [1] "Using Aic" "For Model Selection"

## ^^^ ^^^^^
## "bad" "good"

## -- Very simple insecure crypto --
rot <- function(ch, k = 13) {
    p0 <- function(...) paste(c(...), collapse = "")
    A <- c(letters, LETTERS, "/quotesingle.Var"
    I <- seq_len(k); chartr(p0(A), p0(c(A[-I], A[I])), ch)
}

pw <- "my secret pass phrase"
(crypw <- rot(pw, 13)) #-> you can send this off

## now `\decrypt'
rot(crypw, 54 - 13) # -> the original:
stopifnot(identical(pw, rot(crypw, 54 - 13)))

chkDots

Warn About Extraneous Arguments in the "..." of Its Caller

Description

Warn about extraneous arguments in the ... of its caller. A utility to be used e.g., in S3 methods which need a formal ... argument but do not make any use of it. This helps catching user errors in calling the function in question (which is the caller of chkDots()).

Usage

chkDots(..., which.call = -1, allowed = character(0))

Arguments

... "the dots", as passed from the caller.
which.call passed to sys.call(). A caller may use -2 if the message should mention its caller.
allowed not yet implemented: character vector of named elements in ... which are “allowed” and hence not warned about.

Author(s)

Martin Maechler, first version outside base, June 2012.

See Also

warning, ....

Examples

seq.default ## <- you will see `chkDots(...)`
seq(1,5, foo = "bar") # gives warning via chkDots()

## warning with more than one ...-entry:
density.f <- function(x, ...) NextMethod("density")
x <- density(structure(rnorm(10), class="f"), bar=TRUE, baz=TRUE)
chol  The Choleski Decomposition

Description

Compute the Choleski factorization of a real symmetric positive-definite square matrix.

Usage

chol(x, ...)

## Default S3 method:
chol(x, pivot = FALSE, LINPACK = FALSE, tol = -1, ...)

Arguments

x     an object for which a method exists. The default method applies to numeric (or logical) symmetric, positive-definite matrices.
...
  arguments to be based to or from methods.
pivot Should pivoting be used?
LINPACK logical. Should LINPACK be used (now an error)?
tol   A numeric tolerance for use with pivot = TRUE.

Details

chol is generic: the description here applies to the default method.

Note that only the upper triangular part of x is used, so that $R'R = x$ when x is symmetric.

If pivot = FALSE and x is not non-negative definite an error occurs. If x is positive semi-definite (i.e., some zero eigenvalues) an error will also occur as a numerical tolerance is used.

If pivot = TRUE, then the Choleski decomposition of a positive semi-definite x can be computed. The rank of x is returned as attr(Q, "rank"). Subject to numerical errors. The pivot is returned as attr(Q, "pivot"). It is no longer the case that t(Q) %*% Q equals x. However, setting pivot <- attr(Q, "pivot") and oo <- order(pivot), it is true that t(Q[, oo]) %*% Q[, oo] equals x, or, alternatively, t(Q) %*% Q equals x[pivot, pivot]. See the examples.

The value of tol is passed to LAPACK, with negative values selecting the default tolerance of (usually) nrow(x) * .Machine$double.neg.eps * max(diag(x)). The algorithm terminates once the pivot is less than tol.

Unsuccessful results from the underlying LAPACK code will result in an error giving a positive error code: these can only be interpreted by detailed study of the FORTRAN code.

Value

The upper triangular factor of the Choleski decomposition, i.e., the matrix R such that $R'R = x$ (see example).

If pivoting is used, then two additional attributes "pivot" and "rank" are also returned.
Warning

The code does not check for symmetry. If pivot = TRUE and x is not non-negative definite then there will be a warning message but a meaningless result will occur. So only use pivot = TRUE when x is non-negative definite by construction.

References

See Also

chol2inv for its inverse (without pivoting), backsolve for solving linear systems with upper triangular left sides.

qr, svd for related matrix factorizations.

Examples

```r
( m <- matrix(c(5,1,1,3),2,2) )
( cm <- chol(m) )
t(cm) %% cm #-- = 'm'
crossprod(cm) #-- = 'm'

# now for something positive semi-definite
x <- matrix(c(1:5, (1:5)^2), 5, 2)
x <- cbind(x, x[, 1] + 3*x[, 2])
colnames(x) <- letters[20:22]
m <- crossprod(x)
qr(m)$rank # is 2, as it should be

# chol() may fail, depending on numerical rounding:
# chol() unlike qr() does not use a tolerance. try(chol(m))

(Q <- chol(m, pivot = TRUE))
## we can use this by
pivot <- attr(Q, "pivot")
crossprod(Q[, order(pivot)]) # recover m

## now for a non-positive-definite matrix
( m <- matrix(c(5,-5,-5,3), 2, 2) )
try(chol(m)) # fails
(Q <- chol(m, pivot = TRUE)) # warning
crossprod(Q) # not equal to m
```
**Description**

Invert a symmetric, positive definite square matrix from its Choleski decomposition. Equivalently, compute \((X'X)^{-1}\) from the \((R\) part) of the QR decomposition of \(X\).

**Usage**

```r
chol2inv(x, size = NCOL(x), LINPACK = FALSE)
```

**Arguments**

- `x` a matrix. The first `size` columns of the upper triangle contain the Choleski decomposition of the matrix to be inverted.
- `size` the number of columns of `x` containing the Choleski decomposition.
- `LINPACK` logical. Defunct and gives an error.

**Value**

The inverse of the matrix whose Choleski decomposition was given.

Unsuccessful results from the underlying LAPACK code will result in an error giving a positive error code: these can only be interpreted by detailed study of the FORTRAN code.

**Source**

This is an interface to the LAPACK routine `DPOTRI`. LAPACK is from [https://www.netlib.org/lapack/](https://www.netlib.org/lapack/) and its guide is listed in the references.

**Examples**

```r
cma <- chol(ma <- cbind(1, 1:3, c(1,3,7)))
ma %*% chol2inv(cma)
```
**class**

Object Classes

**Description**

R possesses a simple generic function mechanism which can be used for an object-oriented style of programming. Method dispatch takes place based on the class of the first argument to the generic function.

**Usage**

```r
class(x)
class(x) <- value
unclass(x)
inherits(x, what, which = FALSE)
isa(x, what)
oldClass(x)
oldClass(x) <- value
.class2(x)
```

**Arguments**

- `x` a R object
- `what`, `value` a character vector naming classes. `value` can also be `NULL`.
- `which` logical affecting return value: see ‘Details’.

**Details**

Here, we describe the so called “S3” classes (and methods). For “S4” classes (and methods), see ‘Formal classes’ below.

Many R objects have a `class` attribute, a character vector giving the names of the classes from which the object `inherits`. (Functions `oldClass` and `oldClass<-` get and set the attribute, which can also be done directly.)

If the object does not have a class attribute, it has an implicit class, notably "matrix", "array", "function" or "numeric" or the result of `typeof(x)` (which is similar to `mode(x)`), but for type "language" and `mode"call", where the following extra classes exist for the corresponding function `calls`: if, while, for, =, <-, ., call.

Note that for objects `x` of an implicit (or an S4) class, when a (S3) generic function `foo(x)` is called, method dispatch may use more classes than are returned by `class(x)`, e.g., for a numeric matrix, the `foo.numeric()` method may apply. The exact full `character` vector of the classes which `UseMethod()` uses, is available as `.class2(x)` since R version 4.0.0. (This also applies to S4 objects when S3 dispatch is considered, see below.)

Beware that using `.class2()` for other reasons than didactical, diagnostical or for debugging may rather be a misuse than smart.

**NULL** objects (of implicit class "NULL") cannot have attributes (hence no class attribute) and attempting to assign a class is an error.

When a generic function `fun` is applied to an object with class attribute `c("first","second")`, the system searches for a function called `fun.first` and, if it finds it, applies it to the object. If no
such function is found, a function called `fun.second` is tried. If no class name produces a suitable function, the function `fun.default` is used (if it exists). If there is no class attribute, the implicit class is tried, then the default method.

The function `class` prints the vector of names of classes an object inherits from. Correspondingly, `class<-` sets the classes an object inherits from. Assigning `NULL` removes the class attribute.

`unclass` returns (a copy of) its argument with its class attribute removed. (It is not allowed for objects which cannot be copied, namely environments and external pointers.)

`inherits` indicates whether its first argument inherits from any of the classes specified in the `what` argument. If which is `TRUE` then an integer vector of the same length as `what` is returned. Each element indicates the position in the `class(x)` matched by the element of `what`; zero indicates no match. If which is `FALSE` then `TRUE` is returned by `inherits` if any of the names in what match with any class.

`isa` tests whether `x` is an object of class(es) as given in what by using `is` if `x` is an S4 object, and otherwise giving `TRUE` iff all elements of `class(x)` are contained in what.

All but `inherits` are primitive functions.

### Formal classes

An additional mechanism of **formal classes**, nicknamed “S4”, is available in package **methods** which is attached by default. For objects which have a formal class, its name is returned by `class` as a character vector of length one and method dispatch can happen on several arguments, instead of only the first. However, S3 method selection attempts to treat objects from an S4 class as if they had the appropriate S3 class attribute, as does `inherits`. Therefore, S3 methods can be defined for S4 classes. See the ‘Introduction’ and ‘Methods_for_S3’ help pages for basic information on S4 methods and for the relation between these and S3 methods.

The replacement version of the function sets the class to the value provided. For classes that have a formal definition, directly replacing the class this way is strongly deprecated. The expression `as(object,value)` is the way to coerce an object to a particular class.

The analogue of `inherits` for formal classes is `is`. The two functions behave consistently with one exception: S4 classes can have conditional inheritance, with an explicit test. In this case, `is` will test the condition, but `inherits` ignores all conditional superclasses.

### Note

Functions `oldClass` and `oldClass<-` behave in the same way as functions of those names in S-PLUS 5/6, but in R `UseMethod` dispatches on the class as returned by `class` (with some interpolated classes: see the link) rather than `oldClass`. However, **group generics** dispatch on the `oldClass` for efficiency, and **internal generics** only dispatch on objects for which `is.object` is true.

In older versions of R, assigning a zero-length vector with `class` removed the class: it is now an error (whereas it still works for `oldClass`). It is clearer to always assign `NULL` to remove the class.

### See Also

`UseMethod`, `NextMethod`, ‘group generic’, ‘internal generic’

### Examples

```r
x <- 10
class(x) # "numeric"
oldClass(x) # NULL
inherits(x, "a") # FALSE
```
class(x) <- c("a", "b")
inherits(x,"a") # TRUE
inherits(x, "a", TRUE) # 1
inherits(x, c("a", "b", "c"), TRUE) # 1 2 0

class( quote(pi) ) # "name"
## regular calls
class( quote(sin(pi*x)) ) # "call"
## special calls
class( quote(x <- 1) ) # "<-"
class( quote((1 < 2)) ) # "("
class( quote( if(8<3) pi ) ) # "if"

.col2(pi) # "double" "numeric"
.col2(matrix(1:6, 2,3)) # "matrix" "array" "integer" "numeric"

<table>
<thead>
<tr>
<th>col</th>
<th>Column Indexes</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Description**

Returns a matrix of integers indicating their column number in a matrix-like object, or a factor of column labels.

**Usage**

col(x, as.factor = FALSE)
.

**Arguments**

- **x**
  
a matrix-like object, that is one with a two-dimensional `dim`.
- **dim**
  
a matrix dimension, i.e., an integer valued numeric vector of length two (with non-negative entries).
- **as.factor**
  
a logical value indicating whether the value should be returned as a factor of column labels (created if necessary) rather than as numbers.

**Value**

An integer (or factor) matrix with the same dimensions as `x` and whose `i,j`-th element is equal to `j` (or the `j`-th column label).

**References**

**See Also**

- `row` to get rows; `slice.index` for a general way to get slice indices in an array.
Examples

# extract an off-diagonal of a matrix
ma <- matrix(1:12, 3, 4)
ma[row(ma) == col(ma) + 1]

# create an identity 5-by-5 matrix more slowly than diag(n = 5):
x <- matrix(0, nrow = 5, ncol = 5)
x[row(x) == col(x)] <- 1

(i34 <- .col(3:4))
stopifnot(identical(i34, .col(c(3,4)))) # 'dim' maybe "double"

Colon

Colon Operator

Description

Generate regular sequences.

Usage

from:to
    a:b

Arguments

from starting value of sequence.
to (maximal) end value of the sequence.
a, b factors of the same length.

Details

The binary operator : has two meanings: for factors a:b is equivalent to interaction(a,b) (but the levels are ordered and labelled differently).

For other arguments from:to is equivalent to seq(from, to), and generates a sequence from from to to in steps of 1 or -1. Value to will be included if it differs from from by an integer up to a numeric fuzz of about 1e-7. Non-numeric arguments are coerced internally (hence without dispatching methods) to numeric—complex values will have their imaginary parts discarded with a warning.

Value

For numeric arguments, a numeric vector. This will be of type integer if from is integer-valued and the result is representable in the R integer type, otherwise of type "double" (aka mode "numeric").

For factors, an unordered factor with levels labelled as 1a:1b and ordered lexicographically (that is, 1b varies fastest).

References

(for numeric arguments: S does not have : for factors.)
See Also

seq (a generalization of from:to).

As an alternative to using : for factors, interaction.

For : used in the formal representation of an interaction, see formula.

Examples

1:4
pi:6 # real
6:pi # integer

f1 <- gl(2, 3); f1
f2 <- gl(3, 2); f2
f1:f2 # a factor, the "cross" f1 x f2

colSums

Form Row and Column Sums and Means

Description

Form row and column sums and means for numeric arrays (or data frames).

Usage

colSums (x, na.rm = FALSE, dims = 1)
rowSums (x, na.rm = FALSE, dims = 1)
colMeans(x, na.rm = FALSE, dims = 1)
rowMeans(x, na.rm = FALSE, dims = 1)

.colSums(x, m, n, na.rm = FALSE)
.rowSums(x, m, n, na.rm = FALSE)
.colMeans(x, m, n, na.rm = FALSE)
.rowMeans(x, m, n, na.rm = FALSE)

Arguments

x

an array of two or more dimensions, containing numeric, complex, integer or logical values, or a numeric data frame. For .colSums() etc, a numeric, integer or logical matrix (or vector of length m * n).

na.rm

logical. Should missing values (including NaN) be omitted from the calculations?

dims

integer: Which dimensions are regarded as ‘rows’ or ‘columns’ to sum over. For row*, the sum or mean is over dimensions dims+1,...; for col* it is over dimensions 1:dims.

m, n

the dimensions of the matrix x for .colSums() etc.
Details

These functions are equivalent to use of \texttt{apply} with \texttt{FUN = mean} or \texttt{FUN = sum} with appropriate margins, but are a lot faster. As they are written for speed, they blur over some of the subtleties of \texttt{NaN} and \texttt{NA}. If \texttt{na.rm = FALSE} and either \texttt{NaN} or \texttt{NA} appears in a sum, the result will be one of \texttt{NaN} or \texttt{NA}, but which might be platform-dependent.

Notice that omission of missing values is done on a per-column or per-row basis, so column means may not be over the same set of rows, and vice versa. To use only complete rows or columns, first select them with \texttt{na.omit} or \texttt{complete.cases} (possibly on the transpose of \texttt{x}).

The versions with an initial dot in the name (\texttt{.colSums()} etc) are ‘bare-bones’ versions for use in programming: they apply only to numeric (like) matrices and do not name the result.

Value

A numeric or complex array of suitable size, or a vector if the result is one-dimensional. For the first four functions the \texttt{dimnames} (or names for a vector result) are taken from the original array.

If there are no values in a range to be summed over (after removing missing values with \texttt{na.rm = TRUE}), that component of the output is set to 0 (*Sums*) or \texttt{NaN} (*Means*), consistent with \texttt{sum} and \texttt{mean}.

See Also

\texttt{apply}, \texttt{rowsum}

Examples

```r
## Compute row and column sums for a matrix:
x <- cbind(x1 = 3, x2 = c(4:1, 2:5))
rowSums(x); colSums(x)
dimnames(x)[[1]] <- letters[1:8]
rowSums(x); colSums(x); rowMeans(x); colMeans(x)
x[] <- as.integer(x)
rowSums(x); colSums(x)
x[] <- x < 3
rowSums(x); colSums(x)
x <- cbind(x1 = 3, x2 = c(4:1, 2:5))
x[, 3] <- NA; x[4, 2] <- NA
rowSums(x); colSums(x); rowMeans(x); colMeans(x)
rowSums(x, na.rm = TRUE); colSums(x, na.rm = TRUE)
rowMeans(x, na.rm = TRUE); colMeans(x, na.rm = TRUE)
```

```r
## an array
dim(UCBAdmissions)
rowSums(UCBAdmissions); rowSums(UCBAdmissions, dims = 2)
colSums(UCBAdmissions); colSums(UCBAdmissions, dims = 2)
```

```r
## complex case
x <- cbind(x1 = 3 + 2i, x2 = c(4i:1, 2:5) - 5i)
x[, 3] <- NA; x[4, 2] <- NA
rowSums(x); colSums(x); rowMeans(x); colMeans(x)
rowSums(x, na.rm = TRUE); colSums(x, na.rm = TRUE)
rowMeans(x, na.rm = TRUE); colMeans(x, na.rm = TRUE)
```
commandArgs

### Extract Command Line Arguments

**Description**

Provides access to a copy of the command line arguments supplied when this R session was invoked.

**Usage**

```r
commandArgs(trailingOnly = FALSE)
```

**Arguments**

- `trailingOnly` logical. Should only arguments after `--args` be returned?

**Details**

These arguments are captured before the standard R command line processing takes place. This means that they are the unmodified values. This is especially useful with the `--args` command-line flag to R, as all of the command line after that flag is skipped.

**Value**

A character vector containing the name of the executable and the user-supplied command line arguments. The first element is the name of the executable by which R was invoked. The exact form of this element is platform dependent: it may be the fully qualified name, or simply the last component (or basename) of the application, or for an embedded R it can be anything the programmer supplied. If `trailingOnly = TRUE`, a character vector of those arguments (if any) supplied after `--args`.

**See Also**

`R.home()`, `Startup` and `BATCH`

**Examples**

```r
commandArgs()
## Spawn a copy of this application as it was invoked,
## subject to shell quoting issues
## system(paste(commandArgs(), collapse = " "))
```

---

**comment**

### Query or Set a "comment" Attribute

**Description**

These functions set and query a comment attribute for any R objects. This is typically useful for `data.frames` or model fits.

Contrary to other attributes, the comment is not printed (by `print` or `print.default`). Assigning NULL or a zero-length character vector removes the comment.
Usage

comment(x)
comment(x) <- value

Arguments

x any R object
value a character vector, or NULL.

See Also

attributes and attr for other attributes.

Examples

x <- matrix(1:12, 3, 4)
comment(x) <- c("This is my very important data from experiment #0234",
               "Jun 5, 1998")
x
comment(x)

Comparison

Relational Operators

Description

Binary operators which allow the comparison of values in atomic vectors.

Usage

x < y
x > y
x <= y
x >= y
x == y
x != y

Arguments

x, y atomic vectors, symbols, calls, or other objects for which methods have been written.

Details

The binary comparison operators are generic functions: methods can be written for them individually or via the Ops group generic function. (See Ops for how dispatch is computed.) Comparison of strings in character vectors is lexicographic within the strings using the collating sequence of the locale in use: see locales. The collating sequence of locales such as ‘en_US’ is normally different from ‘C’ (which should use ASCII) and can be surprising. Beware of making any assumptions about the collation order: e.g. in Estonian Z comes between S and T, and collation is not necessarily character-by-character – in Danish aa sorts as a single letter, after z. In Welsh ng
Comparison

may or may not be a single sorting unit: if it is it follows g. Some platforms may not respect the locale and always sort in numerical order of the bytes in an 8-bit locale, or in Unicode code-point order for a UTF-8 locale (and may not sort in the same order for the same language in different character sets). Collation of non-letters (spaces, punctuation signs, hyphens, fractions and so on) is even more problematic.

Character strings can be compared with different marked encodings (see Encoding): they are translated to UTF-8 before comparison.

Raw vectors should not really be considered to have an order, but the numeric order of the byte representation is used.

At least one of \( x \) and \( y \) must be an atomic vector, but if the other is a list \( R \) attempts to coerce it to the type of the atomic vector: this will succeed if the list is made up of elements of length one that can be coerced to the correct type.

If the two arguments are atomic vectors of different types, one is coerced to the type of the other, the (decreasing) order of precedence being character, complex, numeric, integer, logical and raw.

Missing values (\( \text{NA} \) and \( \text{NaN} \) values are regarded as non-comparable even to themselves, so comparisons involving them will always result in \( \text{NA} \). Missing values can also result when character strings are compared and one is not valid in the current collation locale.

Language objects such as symbols and calls are deparsed to character strings before comparison.

Value

A logical vector indicating the result of the element by element comparison. The elements of shorter vectors are recycled as necessary.

Objects such as arrays or time-series can be compared this way provided they are conformable.

S4 methods

These operators are members of the S4 \texttt{Compare} group generic, and so methods can be written for them individually as well as for the group generic (or the \texttt{Ops} group generic), with arguments \texttt{c(e1,e2)}.

Note

Do not use \( == \) and \( != \) for tests, such as in if expressions, where you must get a single \texttt{TRUE} or \texttt{FALSE}. Unless you are absolutely sure that nothing unusual can happen, you should use the \texttt{identical} function instead.

For numerical and complex values, remember \( == \) and \( != \) do not allow for the finite representation of fractions, nor for rounding error. Using \texttt{all.equal} with identical or \texttt{isTRUE} is almost always preferable; see the examples. (This also applies to the other comparison operators.)

These operators are sometimes called as functions as e.g. \( '<' \)(\( x, y \)): see the description of how argument-matching is done in \texttt{Ops}.

References

Collation of character strings is a complex topic. For an introduction see \url{https://en.wikipedia.org/wiki/Collating_sequence}. The \textit{Unicode Collation Algorithm} (\url{https://unicode.org/reports/tr10/}) is likely to be increasingly influential. Where available \( R \) by default makes use of ICU (\url{http://site.icu-project.org/}) for collation (except in a C locale).
Complex Numbers and Basic Functionality

Description

Basic functions which support complex arithmetic in R, in addition to the arithmetic operators +, -, \*, /, and ^. 

Usage

\[
\text{complex}(\text{length.out} = 0, \text{real} = \text{numeric()}, \text{imaginary} = \text{numeric()}, \\
\text{modulus} = 1, \text{argument} = 0) \\
\text{as.complex}(x, ...) \\
\text{is.complex}(x) \\
\text{Re}(z) \\
\text{Im}(z) \\
\text{Mod}(z) \\
\text{Arg}(z) \\
\text{Conj}(z)
\]

See Also

Logic on how to combine results of comparisons, i.e., logical vectors.
factor for the behaviour with factor arguments.
Syntax for operator precedence.
capabilities for whether ICU is available, and icuSetCollate to tune the string collation algorithm when it is.

Examples

```r
x <- stats::rnorm(20)
x < 1
x[x > 0]
x1 <- 0.5 - 0.3
x2 <- 0.3 - 0.1
x1 == x2 # FALSE on most machines
isTRUE(all.equal(x1, x2)) # TRUE everywhere

# range of most 8-bit charsets, as well as of Latin-1 in Unicode
z <- c(32:126, 160:255)
x <- if (l10n_info()$MBCS) {
  intToUtf8(z, multiple = TRUE)
} else rawToChar(as.raw(z), multiple = TRUE)
## by number
writeLines(strwrap(paste(x, collapse=" "), width = 60))
## by locale collation
writeLines(strwrap(paste(sort(x), collapse=" "), width = 60))
```
Complex vectors can be created with `complex`. The vector can be specified either by giving its length, its real and imaginary parts, or modulus and argument. (Giving just the length generates a vector of complex zeroes.)

The functions `Re`, `Im`, `Mod`, `Arg` and `Conj` have their usual interpretation as returning the real part, imaginary part, modulus, argument and complex conjugate for complex values. The modulus and argument are also called the polar coordinates. If $z = x + iy$ with real $x$ and $y$, for $r = \text{Mod}(z) = \sqrt{x^2 + y^2}$, and $\phi = \text{Arg}(z)$, $x = r \cdot \cos(\phi)$ and $y = r \cdot \sin(\phi)$. They are all internal generic primitive functions: methods can be defined for them individually or via the `Complex` group generic.

In addition to the arithmetic operators (see `Arithmetic` $+$, $-$, $*$, $/$, and $^*$, the elementary trigonometric, logarithmic, exponential, square root and hyperbolic functions are implemented for complex values.

Matrix multiplications (`%*%`, `crossprod`, `tcrossprod`) are also defined for complex matrices (`matrix`), and so are `solve`, `eigen` or `svd`.

Internally, complex numbers are stored as a pair of `double` precision numbers, either or both of which can be `NaN` (including `NA`, see `NA_complex_` and above) or plus or minus infinity.

**S4 methods**

`as.complex` is primitive and can have S4 methods set.

`Re`, `Im`, `Mod`, `Arg` and `Conj` constitute the S4 group generic `Complex` and so S4 methods can be set for them individually or via the group generic.

**Note**

Operations and functions involving complex `NaN` mostly rely on the C library’s handling of ‘double complex’ arithmetic, which typically returns `complex(re=NaN, im=NaN)` (but we have not seen a guarantee for that). For $+$ and $-$, R’s own handling works strictly “coordinate wise”.

Operations involving complex `NA`, i.e., `NA_complex_`, return `NA_complex_`. 

---

**Arguments**

- `length.out` numeric. Desired length of the output vector, inputs being recycled as needed.
- `real` numeric vector.
- `imaginary` numeric vector.
- `modulus` numeric vector.
- `argument` numeric vector.
- `x` an object, probably of mode `complex`.
- `z` an object of mode `complex`, or one of a class for which a method has been defined.
- `...` further arguments passed to or from other methods.

**Details**

Complex vectors can be created with `complex`. The vector can be specified either by giving its length, its real and imaginary parts, or modulus and argument. (Giving just the length generates a vector of complex zeroes.)

`as.complex` attempts to coerce its argument to be of complex type: like `as.vector` it strips attributes including names. Up to R versions 3.2.x, all forms of `NA` and `NaN` were coerced to a complex `NA`, i.e., the `NA_complex_` constant, for which both the real and imaginary parts are `NA`. Since R 3.3.0, typically only objects which are `NA` in parts are coerced to complex `NA`, but others with `NaN` parts, are not. As a consequence, complex arithmetic where only `NaN`’s (but no `NA`’s) are involved typically will not give complex `NA` but complex numbers with real or imaginary parts of `NaN`.

Note that `is.complex` and `is.numeric` are never both `TRUE`.

The functions `Re`, `Im`, `Mod`, `Arg` and `Conj` have their usual interpretation as returning the real part, imaginary part, modulus, argument and complex conjugate for complex values. The modulus and argument are also called the polar coordinates. If $z = x + iy$ with real $x$ and $y$, for $r = \text{Mod}(z) = \sqrt{x^2 + y^2}$, and $\phi = \text{Arg}(z)$, $x = r \cdot \cos(\phi)$ and $y = r \cdot \sin(\phi)$. They are all internal generic primitive functions: methods can be defined for them individually or via the `Complex` group generic.

In addition to the arithmetic operators (see `Arithmetic` $+$, $-$, $*$, $/$, and $^*$, the elementary trigonometric, logarithmic, exponential, square root and hyperbolic functions are implemented for complex values.

Matrix multiplications (`%*%`, `crossprod`, `tcrossprod`) are also defined for complex matrices (`matrix`), and so are `solve`, `eigen` or `svd`.

Internally, complex numbers are stored as a pair of `double` precision numbers, either or both of which can be `NaN` (including `NA`, see `NA_complex_` and above) or plus or minus infinity.
### Conditions

#### Condition Handling and Recovery

These functions provide a mechanism for handling unusual conditions, including errors and warnings.

#### Usage

```r
tryCatch(expr, ..., finally)
withCallingHandlers(expr, ...)
globalCallingHandlers(...)
```
signalCondition(cond)

simpleCondition(message, call = NULL)
simpleError (message, call = NULL)
simpleWarning (message, call = NULL)
simpleMessage (message, call = NULL)

errorCondition(message, ..., class = NULL, call = NULL)
warningCondition(message, ..., class = NULL, call = NULL)

## S3 method for class 'condition'
as.character(x, ...)
## S3 method for class 'error'
as.character(x, ...)
## S3 method for class 'condition'
print(x, ...)
## S3 method for class 'restart'
print(x, ...)

conditionCall(c)
## S3 method for class 'condition'
conditionCall(c)
conditionMessage(c)
## S3 method for class 'condition'
conditionMessage(c)

withRestarts(expr, ...)

computeRestarts(cond = NULL)
findRestart(name, cond = NULL)
invokeRestart(r, ...)
tryInvokeRestart(r, ...)
invokeRestartInteractively(r)

isRestart(x)
restartDescription(r)
restartFormals(r)

suspendInterrupts(expr)
allowInterrupts(expr)

.signalSimpleWarning(msg, call)
.signalSimpleError(h, msg, call)
.tryResumeInterrupt()

Arguments

- `c` a condition object.
- `call` call expression.
- `cond` a condition object.
- `expr` expression to be evaluated.
\texttt{finally} expression to be evaluated before returning or exiting.

\texttt{h} function.

\texttt{message} character string.

\texttt{msg} character string.

\texttt{name} character string naming a restart.

\texttt{r} restart object.

\texttt{x} object.

\texttt{class} character string naming a condition class.

\texttt{...} additional arguments; see details below.

**Details**

The condition system provides a mechanism for signaling and handling unusual conditions, including errors and warnings. Conditions are represented as objects that contain information about the condition that occurred, such as a message and the call in which the condition occurred. Currently conditions are S3-style objects, though this may eventually change.

Conditions are objects inheriting from the abstract class \texttt{condition}. Errors and warnings are objects inheriting from the abstract subclasses \texttt{error} and \texttt{warning}. The class \texttt{simpleError} is the class used by \texttt{stop} and all internal error signals. Similarly, \texttt{simpleWarning} is used by \texttt{warning}, and \texttt{simpleMessage} is used by \texttt{message}. The constructors by the same names take a string describing the condition as argument and an optional call. The functions \texttt{conditionMessage} and \texttt{conditionCall} are generic functions that return the message and call of a condition.

The function \texttt{errorCondition} and \texttt{warningCondition} can be used to construct error conditions of a particular class with additional fields specified as the \texttt{...} argument. \texttt{warningCondition} is analogous for warnings.

Conditions are signaled by \texttt{signalCondition}. In addition, the \texttt{stop} and \texttt{warning} functions have been modified to also accept condition arguments.

The function \texttt{tryCatch} evaluates its expression argument in a context where the handlers provided in the \texttt{...} argument are available. The \texttt{finally} expression is then evaluated in the context in which \texttt{tryCatch} was called; that is, the handlers supplied to the current \texttt{tryCatch} call are not active when the \texttt{finally} expression is evaluated.

Handlers provided in the \texttt{...} argument to \texttt{tryCatch} are established for the duration of the evaluation of \texttt{expr}. If no condition is signaled when evaluating \texttt{expr} then \texttt{tryCatch} returns the value of the expression.

If a condition is signaled while evaluating \texttt{expr} then established handlers are checked, starting with the most recently established ones, for one matching the class of the condition. When several handlers are supplied in a single \texttt{tryCatch} then the first one is considered more recent than the second. If a handler is found then control is transferred to the \texttt{tryCatch} call that established the handler, the handler found and all more recent handlers are disestablished, the handler is called with the condition as its argument, and the result returned by the handler is returned as the value of the \texttt{tryCatch} call.

Calling handlers are established by \texttt{withCallingHandlers}. If a condition is signaled and the applicable handler is a calling handler, then the handler is called by \texttt{signalCondition} in the context where the condition was signaled but with the available handlers restricted to those below the handler called in the handler stack. If the handler returns, then the next handler is tried; once the last handler has been tried, \texttt{signalCondition} returns NULL.

\texttt{globalCallingHandlers} establishes calling handlers globally. These handlers are only called as a last resort, after the other handlers dynamically registered with \texttt{withCallingHandlers} have
been invoked. They are called before the *error* global option (which is the legacy interface for global handling of errors). Registering the same handler multiple times moves that handler on top of the stack, which ensures that it is called first. Global handlers are a good place to define a general purpose logger (for instance saving the last error object in the global workspace) or a general recovery strategy (e.g. installing missing packages via the *retry_loadNamespace* restart).

Like `withCallingHandlers` and `tryCatch`, `globalCallingHandlers` takes named handlers. Unlike these functions, it also has an *options*-like interface: you can establish handlers by passing a single list of named handlers. To unregister all global handlers, supply a single `NULL`. The list of deleted handlers is returned invisibly. Finally, calling `globalCallingHandlers` without arguments returns the list of currently established handlers, visibly.

User interrupts signal a condition of class `interrupt` that inherits directly from class `condition` before executing the default interrupt action.

Restarts are used for establishing recovery protocols. They can be established using `withRestarts`. One pre-established restart is an *abort* restart that represents a jump to top level.

`findRestart` and `computeRestarts` find the available restarts. `findRestart` returns the most recently established restart of the specified name. `computeRestarts` returns a list of all restarts. Both can be given a condition argument and will then ignore restarts that do not apply to the condition.

`invokeRestart` transfers control to the point where the specified restart was established and calls the restart’s handler with the arguments, if any, given as additional arguments to `invokeRestart`. The restart argument to `invokeRestart` can be a character string, in which case `findRestart` is used to find the restart. If no restart is found, an error is thrown.

`tryInvokeRestart` is a variant of `invokeRestart` that returns silently when the restart cannot be found with `findRestart`. Because a condition of a given class might be signalled with arbitrary protocols (error, warning, etc), it is recommended to use this permissive variant whenever you are handling conditions signalled from a foreign context. For instance, invocation of a "muffleWarning" restart should be optional because the warning might have been signalled by the user or from a different package with the stop or message protocols. Only use `invokeRestart` when you have control of the signalling context, or when it is a logical error if the restart is not available.

New restarts for `withRestarts` can be specified in several ways. The simplest is in `name = function` form where the function is the handler to call when the restart is invoked. Another simple variant is as `name = string` where the string is stored in the *description* field of the restart object returned by `findRestart`; in this case the handler ignores its arguments and returns `NULL`. The most flexible form of a restart specification is as a list that can include several fields, including *handler*, *description*, and *test*. The *test* field should contain a function of one argument, a condition, that returns `TRUE` if the restart applies to the condition and `FALSE` if it does not; the default function returns `TRUE` for all conditions.

One additional field that can be specified for a restart is `interactive`. This should be a function of no arguments that returns a list of arguments to pass to the restart handler. The list could be obtained by interacting with the user if necessary. The function `invokeRestartInteractively` calls this function to obtain the arguments to use when invoking the restart. The default interactive method queries the user for values for the formal arguments of the handler function.

Interrupts can be suspended while evaluating an expression using `suspendInterrupts`. Sub-expression can be evaluated with interrupts enabled using `allowInterrupts`. These functions can be used to make sure cleanup handlers cannot be interrupted.

`.signalSimpleWarning`, `.handleSimpleError`, and `.tryResumeInterrupt` are used internally and should not be called directly.
conflicts

Search for Masked Objects on the Search Path

Description

conflicts reports on objects that exist with the same name in two or more places on the search path, usually because an object in the user’s workspace or a package is masking a system object of the same name. This helps discover unintentional masking.

Usage

conflicts(where = search(), detail = FALSE)

Arguments

where A subset of the search path, by default the whole search path.
detail If TRUE, give the masked or masking functions for all members of the search path.
Value

If `detail = FALSE`, a character vector of masked objects. If `detail = TRUE`, a list of character vectors giving the masked or masking objects in that member of the search path. Empty vectors are omitted.

Examples

```r
lm <- 1:3
conflicts(), TRUE)
## gives something like
# $.GlobalEnv
# [1] "lm"
#
# $package:base
# [1] "lm"

## Remove things from your "workspace" that mask others:
remove(list = conflicts(detail = TRUE)$.$GlobalEnv)
```

connections  

Functions to Manipulate Connections (Files, URLs, ...)

Description

Functions to create, open and close connections, i.e., “generalized files”, such as possibly compressed files, URLs, pipes, etc.

Usage

```r
file(description = "", open = "", blocking = TRUE,
    encoding = getOption("encoding"), raw = FALSE,
    method = getOption("url.method", "default"))

url(description, open = "", blocking = TRUE,
    encoding = getOption("encoding"),
    method = getOption("url.method", "default"),
    headers = NULL)

gzfile(description, open = "", encoding = getOption("encoding"),
    compression = 6)

bzfile(description, open = "", encoding = getOption("encoding"),
    compression = 9)

xzfile(description, open = "", encoding = getOption("encoding"),
    compression = 6)

unz(description, filename, open = "", encoding = getOption("encoding"))

pipe(description, open = "", encoding = getOption("encoding"))

fifo(description, open = "", blocking = FALSE,
    encoding = getOption("encoding"))
```
encoding = getOption("encoding"))

socketConnection(host = "localhost", port, server = FALSE,
    blocking = FALSE, open = "a+",
    encoding = getOption("encoding"),
    timeout = getOption("timeout"))

serverSocket(port)

socketAccept(socket, blocking = FALSE, open = "a+",
    encoding = getOption("encoding"),
    timeout = getOption("timeout"))

open(con, ...)
## S3 method for class 'connection'
open(con, open = "r", blocking = TRUE, ...)

close(con, ...)
## S3 method for class 'connection'
close(con, type = "rw", ...)

flush(con)

isOpen(con, rw = "")
isIncomplete(con)

socketTimeout(socket, timeout = -1)

Arguments

description character string. A description of the connection: see ‘Details’.
open character string. A description of how to open the connection (if it should be
opened initially). See section ‘Modes’ for possible values.
blocking logical. See the ‘Blocking’ section.
encoding The name of the encoding to be assumed. See the ‘Encoding’ section.
raw logical. If true, a ‘raw’ interface is used which will be more suitable for argu-
m ents which are not regular files, e.g. character devices. This suppresses the
check for a compressed file when opening for text-mode reading, and asserts
that the ‘file’ may not be seekable.
method character string, partially matched to c("default","internal","wininet","libcurl"): see ‘Details’.
headers named character vector of HTTP headers to use in HTTP requests. It is
ignored for non-HTTP URLs. The User-Agent header, coming from the
HTTPUserAgent option (see options) is used as the first header, automatically.
compression integer in 0–9. The amount of compression to be applied when writing, from
none to maximal available. For xzfile can also be negative: see the ‘Compress-
ion’ section.
timeout numeric: the timeout (in seconds) to be used for this connection. Beware that
some OSes may treat very large values as zero: however the POSIX standard
requires values up to 31 days to be supported.
connections

filename a filename within a zip file.
host character string. Host name for the port.
port integer. The TCP port number.
server logical. Should the socket be a client or a server?
socket a server socket listening for connections.
con a connection.
type character string. Currently ignored.
rw character string. Empty or "read" or "write", partial matches allowed.
... arguments passed to or from other methods.

Details

The first eleven functions create connections. By default the connection is not opened (except for a socket connection created by socketConnection or socketAccept and for server socket connection created by serverSocket), but may be opened by setting a non-empty value of argument open.

For file the description is a path to the file to be opened or a complete URL (when it is the same as calling url), or "" (the default) or "clipboard" (see the ‘Clipboard’ section). Use “stdin” to refer to the C-level ‘standard input’ of the process (which need not be connected to anything in a console or embedded version of R, and is not in Rgui on Windows). See also stdin() for the subtly different R-level concept of stdin. See nullfile() for a platform-independent way to get filename of the null device.

For url the description is a complete URL including scheme (such as ‘http://’, ‘https://’, ‘ftp://’ or ‘file://’). Method “internal” is that available since connections were introduced, method "wininet" is only available on Windows (it uses the WinInet functions of that OS) and method "libcurl" (using the library of that name: https://curl.haxx.se/libcurl/) is required on a Unix-alike but optional on Windows. Method "default" uses method "internal" for ‘file:’ URLs and "libcurl" for ‘ftps:’ URLs. On a Unix-alike it uses "libcurl" for ‘http:’, ‘https:’ and ‘ftp:’ URLs; on Windows “wininet” for ‘http:’, ‘ftp:’ and ‘https:’ URLs. Proxies can be specified: see download.file.

For gzf the description is the path to a file compressed by gzip: it can also open for reading uncompressed files and those compressed by bzip2, xz or lzma.

For bzfile the description is the path to a file compressed by bzip2.

For zfile the description is the path to a file compressed by xz (https://en.wikipedia.org/wiki/Xz) or (for reading only) lzma (https://en.wikipedia.org/wiki/LZMA).

unz reads (only) single files within zip files, in binary mode. The description is the full path to the zip file, with ‘.zip’ extension if required.

For pipe the description is the command line to be piped to or from. This is run in a shell, on Windows that specified by the COMSPEC environment variable.

For fifo the description is the path of the fifo. (Support for fifo connections is optional but they are available on most Unix platforms and on Windows.)

The intention is that file and gzf can be used generally for text input (from files, ‘http://’ and ‘https://’ URLs) and binary input respectively.

open, close and seek are generic functions: the following applies to the methods relevant to connections.

open opens a connection. In general functions using connections will open them if they are not open, but then close them again, so to leave a connection open call open explicitly.
connections

close closes and destroys a connection. This will happen automatically in due course (with a warning) if there is no longer an R object referring to the connection.

A maximum of 128 connections can be allocated (not necessarily open) at any one time. Three of these are pre-allocated (see stdout). The OS will impose limits on the numbers of connections of various types, but these are usually larger than 125.

flush flushes the output stream of a connection open for write/append (where implemented, currently for file and clipboard connections, stdout and stderr).

If for a file or (on most platforms) a fifo connection the description is "", the file/fifo is immediately opened (in "w+" mode unless open = "wb" is specified) and unlinked from the file system. This provides a temporary file/fifo to write to and then read from.

socketConnection(server=TRUE) creates a new temporary server socket listening on the given port. As soon as a new socket connection is accepted on that port, the server socket is automatically closed.

serverSocket creates a listening server socket which can be used for accepting multiple socket connections by socketAccept. To stop listening for new connections, a server socket needs to be closed explicitly by close.

socketTimeout sets connection timeout of a socket connection. A negative timeout can be given to query the old value.

Value

file, pipe, fifo, url, gzfile, bzfile, xzfile, unz, socketConnection, socketAccept and serverSocket return a connection object which inherits from class "connection" and has a first more specific class.

open and flush return NULL, invisibly.

close returns either NULL or an integer status, invisibly. The status is from when the connection was last closed and is available only for some types of connections (e.g., pipes, files and fifos): typically zero values indicate success. Negative values will result in a warning; if writing, these may indicate write failures and should not be ignored.

isOpen returns a logical value, whether the connection is currently open.

isIncomplete returns a logical value, whether the last read attempt was blocked, or for an output text connection whether there is unflushed output.

socketTimeout returns the old timeout value of a socket connection.

URLs

url and file support URL schemes ‘file://’, ‘http://’, ‘https://’ and ‘ftp://’.

method = "libcurl" allows more schemes: exactly which schemes is platform-dependent (see libcurlVersion), but all Unix-alike platforms will support ‘https://’ and most platforms will support ‘ftps://’.

Most methods do not percent-encode special characters such as spaces in ‘http://’ URLs (see URLencode), but it seems the “wininet” method does.

A note on ‘file://’ URLs. The most general form (from RFC1738) is ‘file://host/path/to/file’, but R only accepts the form with an empty host field referring to the local machine.

On a Unix-alike, this is then ‘file:///path/to/file’, where ‘path/to/file’ is relative to ‘/’. So although the third slash is strictly part of the specification not part of the path, this can be regarded as a way to specify the file ‘/path/to/file’. It is not possible to specify a relative path using a file URL.
In this form the path is relative to the root of the filesystem, not a Windows concept. The standard form on Windows is ‘file:///d:/R/repos’: for compatibility with earlier versions of R and Unix versions, any other form is parsed as R as ‘file://’ plus path_to_file. Also, backslashes are accepted within the path even though RFC1738 does not allow them.

No attempt is made to decode a percent-encoded ‘file:’ URL: call URLdecode if necessary.

All the methods attempt to follow redirected HTTP URLs, but the "internal" method is unable to follow redirections to HTTPS URLs.

Server-side cached data is always accepted.

Function download.file and several contributed packages provide more comprehensive facilities to download from URLs.

**Modes**

Possible values for the argument open are

"r" or "rt" Open for reading in text mode.

"w" or "wt" Open for writing in text mode.

"a" or "at" Open for appending in text mode.

"rb" Open for reading in binary mode.

"wb" Open for writing in binary mode.

"ab" Open for appending in binary mode.

"r+b", "r+b" Open for reading and writing.

"w+b", "w+b" Open for reading and writing, truncating file initially.

"a+b", "a+b" Open for reading and appending.

Not all modes are applicable to all connections: for example URLs can only be opened for reading. Only file and socket connections can be opened for both reading and writing. An unsupported mode is usually silently substituted.

If a file or fifo is created on a Unix-alike, its permissions will be the maximal allowed by the current setting of umask (see Sys.umask).

For many connections there is little or no difference between text and binary modes. For file-like connections on Windows, translation of line endings (between LF and CRLF) is done in text mode only (but text read operations on connections such as readLines, scan and source work for any form of line ending). Various R operations are possible in only one of the modes: for example pushBack is text-oriented and is only allowed on connections open for reading in text mode, and binary operations such as readBin, load and save can only be done on binary-mode connections.

The mode of a connection is determined when actually opened, which is deferred if open = "" is given (the default for all but socket connections). An explicit call to open can specify the mode, but otherwise the mode will be "r". (gzfile, bzfile and xzfile connections are exceptions, as the compressed file always has to be opened in binary mode and no conversion of line-endings is done even on Windows, so the default mode is interpreted as "rb"). Most operations that need write access or text-only or binary-only mode will override the default mode of a non-yet-open connection.

Append modes need to be considered carefully for compressed-file connections. They do not produce a single compressed stream on the file, but rather append a new compressed stream to the file. Readers may or may not read beyond end of the first stream: currently R does so for gzfile, bzfile and xzfile connections.
Compression

R supports gzip, bzip2 and xz compression (also read-only support for its precursor, lzma compression).

For reading, the type of compression (if any) can be determined from the first few bytes of the file. Thus for file(raw = FALSE) connections, if open is "", "r" or "rt" the connection can read any of the compressed file types as well as uncompressed files. (Using "rb" will allow compressed files to be read byte-by-byte.) Similarly, gzfile connections can read any of the forms of compression and uncompressed files in any read mode.

(The type of compression is determined when the connection is created if open is unspecified and a file of that name exists. If the intention is to open the connection to write a file with a different form of compression under that name, specify open = "w" when the connection is created or unlink the file before creating the connection.)

For write-mode connections, compress specifies how hard the compressor works to minimize the file size, and higher values need more CPU time and more working memory (up to ca 800Mb for xzfile(compress = 9)). For xzfile negative values of compress correspond to adding the xz argument ’-e’: this takes more time (double?) to compress but may achieve (slightly) better compression. The default (6) has good compression and modest (100Mb memory) usage: but if you are using xz compression you are probably looking for high compression.

Choosing the type of compression involves tradeoffs: gzip, bzip2 and xz are successively less widely supported, need more resources for both compression and decompression, and achieve more compression (although individual files may buck the general trend). Typical experience is that bzip2 compression is 15% better on text files than gzip compression, and xz with maximal compression 30% better. The experience with R save files is similar, but on some large ‘.rda’ files xz compression is much better than the other two. With current computers decompression times even with compress = 9 are typically modest and reading compressed files is usually faster than uncompressed ones because of the reduction in disc activity.

Encoding

The encoding of the input/output stream of a connection can be specified by name in the same way as it would be given to iconv: see that help page for how to find out what encoding names are recognized on your platform. Additionally, "" and "native.enc" both mean the ‘native’ encoding, that is the internal encoding of the current locale and hence no translation is done.

When writing to a text connection, the connections code always assumes its input is in native encoding, so e.g. writeLines has to convert text to native encoding. writeLines does not do the conversion when useBytes=TRUE (for expert use only), but the connections code still behaves as if the text was in native encoding, so any attempt to convert encoding (encoding argument other than "" and "native.enc") in connections will produce incorrect results.

When reading from a text connection, the connections code, after re-encoding based on the encoding argument, returns text that is assumed to be in native encoding; an encoding mark is only added by functions that read from the connection, so e.g. readLines can be instructed to mark the text as "UTF-8" or "latin1", but readLines does no further conversion. To allow reading text in "UTF-8" on a system that cannot represent all such characters in native encoding (currently only Windows), a connection can be internally configured to return the read text in UTF-8 even though it is not the native encoding; currently readLines and scan use this feature when given a connection that is not yet open and, when using the feature, they unconditionally mark the text as "UTF-8".

Re-encoding only works for connections in text mode: reading from a connection with re-encoding specified in binary mode will read the stream of bytes, but mixing text and binary mode reads (e.g., mixing calls to readLines and readChar) is likely to lead to incorrect results.
The encodings "UCS-2LE" and "UTF-16LE" are treated specially, as they are appropriate values for Windows ‘Unicode’ text files. If the first two bytes are the Byte Order Mark \texttt{0xFEFF} then these are removed as some implementations of \texttt{iconv} do not accept BOMs. Note that whereas most implementations will handle BOMs using encoding "UCS-2" and choose the appropriate byte order, some (including earlier versions of glibc) will not. There is a subtle distinction between "UTF-16" and "UCS-2" (see \url{https://en.wikipedia.org/wiki/UTF-16}): the use of characters in the ‘Supplementary Planes’ which need surrogate pairs is very rare so "UCS-2LE" is an appropriate first choice (as it is more widely implemented).

As from \texttt{R} 3.0.0 the encoding "UTF-8-BOM" is accepted for reading and will remove a Byte Order Mark if present (which it often is for files and webpages generated by Microsoft applications). If a BOM is required (it is not recommended) when writing it should be written explicitly, e.g. \texttt{writeChar("\uFEFF",con,eos = NULL)} or \texttt{writeBin(as.raw(c(0xEF,0xBB,0xBF)),binary_con)}.

Encoding names "utf8", "mac" and "macroman" are not portable, and not supported on all current \texttt{R} platforms. "UTF-8" is portable and "macintosh" is the official (and most widely supported) name for 'Mac Roman'. (As from \texttt{R} 3.4.0, \texttt{R} maps "utf8" to "UTF-8" internally.)

Requesting a conversion that is not supported is an error, reported when the connection is opened. Exactly what happens when the requested translation cannot be done for invalid input is in general undocumented. On output the result is likely to be that up to the error, with a warning. On input, it will most likely be all or some of the input up to the error.

It may be possible to deduce the current native encoding from \texttt{Sys.getlocale("LC_CTYPE")}, but not all OSes record it.

**Blocking**

Whether or not the connection blocks can be specified for file, url (default yes), fifo and socket connections (default not).

In blocking mode, functions using the connection do not return to the \texttt{R} evaluator until the read/write is complete. In non-blocking mode, operations return as soon as possible, so on input they will return with whatever input is available (possibly none) and for output they will return whether or not the write succeeded.

The function \texttt{readLines} behaves differently in respect of incomplete last lines in the two modes: see its help page.

Even when a connection is in blocking mode, attempts are made to ensure that it does not block the event loop and hence the operation of GUI parts of \texttt{R}. These do not always succeed, and the whole \texttt{R} process will be blocked during a DNS lookup on Unix, for example.

Most blocking operations on HTTP/FTP URLs and on sockets are subject to the timeout set by \texttt{options("timeout")}. Note that this is a timeout for no response, not for the whole operation. The timeout is set at the time the connection is opened (more precisely, when the last connection of that type – ‘http’, ‘ftp’ or socket – was opened).

**Fifos**

Fifos default to non-blocking. That follows S version 4 and is probably most natural, but it does have some implications. In particular, opening a non-blocking fifo connection for writing (only) will fail unless some other process is reading on the fifo.

Opening a fifo for both reading and writing (in any mode: one can only append to fifos) connects both sides of the fifo to the \texttt{R} process, and provides an similar facility to \texttt{file()}. 
connections

Clipboard

file can be used with description = "clipboard" in mode "r" only. This reads the X11 primary selection (see https://specifications.freedesktop.org/clipboards-spec/clipboards-latest.txt), which can also be specified as "X11_primary" and the secondary selection as "X11_secondary". On most systems the clipboard selection (that used by ‘Copy’ from an ‘Edit’ menu) can be specified as "X11_clipboard".

When a clipboard is opened for reading, the contents are immediately copied to internal storage in the connection.

Unix users wishing to write to one of the X11 selections may be able to do so via xclip (https://sourceforge.net/projects/xclip/) or xsel (http://www.vergenet.net/~conrad/software/xsel/), for example by pipe("xclip -i","w") for the primary selection.

macOS users can use pipe("pbpaste") and pipe("pbcopy","w") to read from and write to that system’s clipboard.

File paths

In most cases these are translated to the native encoding.

The exceptions are file and pipe on Windows, where a description which is marked as being in UTF-8 is passed to Windows as a ‘wide’ character string. This allows files with names not in the native encoding to be opened on file systems which use Unicode file names (such as NTFS but not FAT32).

Note

R’s connections are modelled on those in S version 4 (see Chambers, 1998). However R goes well beyond the S model, for example in output text connections and URL, compressed and socket connections. The default open mode in R is "r" except for socket connections. This differs from S, where it is the equivalent of "r+", known as "*".

On (rare) platforms where vsnprintf does not return the needed length of output there is a 100,000 byte output limit on the length of a line for text output on fifo, gzfile, bzfile and xzfile connections: longer lines will be truncated with a warning.

**Examples**

```r
zzfil <- tempfile(fileext = "data")
zz <- file(zzfil, "w") # open an output file connection
cat("TITLE extra line", "2 3 5 7", "", "11 13 17", file = zz, sep = "\n")
cat("One more line\n", file = zz)
close(zz)
readlines(zzfil)
unlink(zzfil)

zzfil <- tempfile(fileext = "gz")
zz <- gzfile(zzfil, "w") # compressed file
cat("TITLE extra line", "2 3 5 7", "", "11 13 17", file = zz, sep = "\n")
close(zz)
readlines(zz <- gzfile(zzfil))
close(zz)
unlink(zzfil)
zz # an invalid connection

zzfil <- tempfile(fileext = "bz2")
zz <- bzfile(zzfil, "w") # bzip2-ed file
```  
```
cat("TITLE extra line", "2 3 5 7", "", "11 13 17", file = zz, sep = "\n")
close(zz)
zz # print() method: invalid connection
print(readLines(zz <- bzfile(zzfil))))
close(zz)
unlink(zzfil)
```

```r
## An example of a file open for reading and writing
Tpath <- tempfile("test")
Tfile <- file(Tpath, "w+")
c(isOpen(Tfile, "r"), isOpen(Tfile, "w")) # both TRUE
cat("abc\n\ndef\n", file = Tfile)
readLines(Tfile)
seek(Tfile, 0, rw = "r") # reset to beginning
readLines(Tfile)
cat("ghi\n", file = Tfile)
readLines(Tfile)
Tfile # -> print() : "valid" connection
close(Tfile)
Tfile # -> print() : "invalid" connection
unlink(Tpath)
```

```r
## We can do the same thing with an anonymous file.
Tfile <- file()
cat("abc\n\ndef\n", file = Tfile)
readLines(Tfile)
close(Tfile)
```

```r
## Not run: ## fifo example -- may hang even with OS support for fifos
if(capabilities("fifo")) {
  zzfil <- tempfile(fileext = "-fifo")

### Constants

<table>
<thead>
<tr>
<th>Description</th>
<th>Built-in Constants</th>
</tr>
</thead>
<tbody>
<tr>
<td>Constants built into R.</td>
<td></td>
</tr>
</tbody>
</table>

### Usage

- `LETTERS`
- `letters`
- `month.abb`
- `month.name`
- `pi`

### Details

R has a small number of built-in constants.

The following constants are available:

- `LETTERS`: the 26 upper-case letters of the Roman alphabet;
- `letters`: the 26 lower-case letters of the Roman alphabet;
- `month.abb`: the three-letter abbreviations for the English month names;
- `month.name`: the English names for the months of the year;
- `pi`: the ratio of the circumference of a circle to its diameter.

These are implemented as variables in the base namespace taking appropriate values.

### References

- `DateTimeClasses`.
- `Quotes` for the parsing of character constants, `NumericConstants` for numeric constants.
Examples

## John Machin (ca 1706) computed pi to over 100 decimal places
## using the Taylor series expansion of the second term of
## \( \pi = 4 \times (4 \times \text{atan}(1/5) - \text{atan}(1/239)) \)

## months in English
month.name
## months in your current locale
format(ISOdate(2000, 1:12, 1), "%B")
format(ISOdate(2000, 1:12, 1), "%b")

---

**contributors**  
*R Project Contributors*

**Description**

The R Who-is-who, describing who made significant contributions to the development of R.

**Usage**

`contributors()`

---

**Control**

*Control Flow*

**Description**

These are the basic control-flow constructs of the R language. They function in much the same way as control statements in any Algol-like language. They are all reserved words.

**Usage**

`if(cond) expr`  
`if(cond) cons.expr else alt.expr`

`for(var in seq) expr`  
`while(cond) expr`  
`repeat expr`  
`break`  
`next`

**Arguments**

- **cond**: A length-one logical vector that is not NA. Conditions of length greater than one are currently accepted with a warning, but only the first element is used. An error is signalled instead when the environment variable `_R_CHECK_LENGTH_1_CONDITION_` is set to true. Other types are coerced to logical if possible, ignoring any class.

- **var**: A syntactical name for a variable.
seq
An expression evaluating to a vector (including a list and an expression) or to a pairlist or NULL. A factor value will be coerced to a character vector. As from R 4.0.0 this can be a long vector.

expr, cons.expr, alt.expr
An expression in a formal sense. This is either a simple expression or a so-called compound expression, usually of the form \( \{ \text{expr1} ; \text{expr2} \} \).

Details
break breaks out of a for, while or repeat loop; control is transferred to the first statement outside the inner-most loop. next halts the processing of the current iteration and advances the looping index. Both break and next apply only to the innermost of nested loops.

Note that it is a common mistake to forget to put braces (\( \{ \ldots \} \)) around your statements, e.g., after if(...) or for(...). In particular, you should not have a newline between \} and else to avoid a syntax error in entering a if ... else construct at the keyboard or via source. For that reason, one (somewhat extreme) attitude of defensive programming is to always use braces, e.g., for if clauses.

The seq in a for loop is evaluated at the start of the loop; changing it subsequently does not affect the loop. If seq has length zero the body of the loop is skipped. Otherwise the variable var is assigned in turn the value of each element of seq. You can assign to var within the body of the loop, but this will not affect the next iteration. When the loop terminates, var remains as a variable containing its latest value.

Value
if returns the value of the expression evaluated, or NULL invisibly if none was (which may happen if there is no else).

for, while and repeat return NULL invisibly. for sets var to the last used element of seq, or to NULL if it was of length zero.

break and next do not return a value as they transfer control within the loop.

ifelse, switch for other ways to control flow.

Examples
for(i in 1:5) print(1:i)
for(n in c(2,5,10,20,50)) {
  x <- stats::rnorm(n)
  cat(n, " : ", sum(x^2), "\n", sep = ""
}
f <- factor(sample(letters[1:5], 10, replace = TRUE))
for(i in unique(f)) print(i)
Copyrights of Files Used to Build R

Description

R is released under the ‘GNU Public License’: see license for details. The license describes your right to use R. Copyright is concerned with ownership of intellectual rights, and some of the software used has conditions that the copyright must be explicitly stated: see the ‘Details’ section. We are grateful to these people and other contributors (see contributors) for the ability to use their work.

Details

The file ‘R_HOME/COPYRIGHTS’ lists the copyrights in full detail.

crossprod

Matrix Crossproduct

Description

Given matrices x and y as arguments, return a matrix cross-product. This is formally equivalent to (but usually slightly faster than) the call t(x) %*% y (crossprod) or x %*% t(y) (tcrossprod).

Usage

```r
crossprod(x, y = NULL)
tcrossprod(x, y = NULL)
```

Arguments

- `x, y` numeric or complex matrices (or vectors): `y = NULL` is taken to be the same matrix as `x`. Vectors are promoted to single-column or single-row matrices, depending on the context.

Value

A double or complex matrix, with appropriate dimnames taken from x and y.

Note

When x or y are not matrices, they are treated as column or row matrices, but their names are usually not promoted to dimnames. Hence, currently, the last example has empty dimnames.

In the same situation, these matrix products (also `%*%`) are more flexible in promotion of vectors to row or column matrices, such that more cases are allowed, since R 3.2.0.

The propagation of NaN/Inf values, precision, and performance of matrix products can be controlled by `options("matprod")`. 
Cstack_info

References

\%\*\% and outer product \%o\%.

Examples

```r
(z <- crossprod(1:4))  # = sum(1 + 2^2 + 3^2 + 4^2)
drop(z)                 # scalar
x <- 1:4; names(x) <- letters[1:4]; x
tcrossprod(as.matrix(x)) # is identical(tcrossprod(as.matrix(x)),
crossprod(t(x)))
tcrossprod(x)           # no dimnames

m <- matrix(1:6, 2,3) ; v <- 1:3; v2 <- 2:1
stopifnot(identical(tcrossprod(v, m), v %*% t(m)),
           identical(tcrossprod(v, m), crossprod(v, t(m))),
           identical(crossprod(m, v2), t(m) %*% v2))
```

Cstack_info

Report Information on C Stack Size and Usage

Description

Report information on the C stack size and usage (if available).

Usage

Cstack_info()

Details

On most platforms, C stack information is recorded when R is initialized and used for stack-checking. If this information is unavailable, the size will be returned as NA, and stack-checking is not performed.

The information on the stack base address is thought to be accurate on Windows, Linux (using glibc), macOS and FreeBSD but a heuristic is used on other platforms. Because this might be slightly inaccurate, the current usage could be estimated as negative. (The heuristic is not used on embedded uses of R on platforms where the stack base information is not thought to be accurate.)

The ‘evaluation depth’ is the number of nested R expressions currently under evaluation: this has a limit controlled by options("expressions").
Value

An integer vector. This has named elements

- **size**: The size of the stack (in bytes), or NA if unknown.
- **current**: The estimated current usage (in bytes), possibly NA.
- **direction**: 1 (stack grows down, the usual case) or -1 (stack grows up).
- **eval_depth**: The current evaluation depth (including two calls for the call to Cstack_info).

Examples

Cstack_info()

---

**cumsum**

*Cumulative Sums, Products, and Extremes*

Description

Returns a vector whose elements are the cumulative sums, products, minima or maxima of the elements of the argument.

Usage

- `cumsum(x)`
- `cumprod(x)`
- `cummax(x)`
- `cummin(x)`

Arguments

- **x**: a numeric or complex (not cummin or cummax) object, or an object that can be coerced to one of these.

Details

These are generic functions: methods can be defined for them individually or via the Math group generic.

Value

A vector of the same length and type as x (after coercion), except that `cumprod` returns a numeric vector for integer input (for consistency with `*`). Names are preserved.

An NA value in x causes the corresponding and following elements of the return value to be NA, as does integer overflow in `cumsum` (with a warning).

S4 methods

`cumsum` and `cumprod` are S4 generic functions: methods can be defined for them individually or via the Math group generic. `cummax` and `cummin` are individually S4 generic functions.
References

Examples

cumsum(1:10)
cumprod(1:10)
cummin(c(3:1, 2:0, 4:2))
cummax(c(3:1, 2:0, 4:2))

curlGetHeaders

Retrieve Headers from URLs

Description

Retrieve the headers for a URL for a supported protocol such as http://, ftp://, https:// and ftps://. An optional function not supported on all platforms.

Usage

curlGetHeaders(url, redirect = TRUE, verify = TRUE,
    timeout = 0L, TLS = "")

Arguments

url character string specifying the URL.
redirect logical: should redirections be followed?
verify logical: should certificates be verified as valid and applying to that host?
timeout integer: the maximum time in seconds the request is allowed to take. Non-positive and invalid values are ignored (including the default). (Added in R 4.1.0.)
TLS character: the minimum version of the TLS protocol to be used for https:// URLs: the default ("") is no restriction beyond that of the underlying libcurl (usually 1.0). Other valid values are "1.1", "1.2" (both for libcurl 7.34.0 and later) and "1.3" (7.52.0 and later), if supported by the underlying version of libcurl and the SSL library it uses.

Details

This reports what curl -I -L or curl -I would report. For a ftp:// URL the ‘headers’ are a record of the conversation between client and server before data transfer.

Only 500 header lines will be reported: there is a limit of 20 redirections so this should suffice (and even 20 would indicate problems).

If argument timeout is not set to a positive integer this uses getOption("timeout") which defaults to 60 seconds. As the request cannot be interrupted you may want to consider a shorter value.

To see all the details of the interaction with the server(s) set options(internet.info = 1).

HTTP[S] servers are allowed to refuse requests to read the headers and some do: this will result in a status of 405.
For possible issues with secure URLs (especially on Windows) see `download.file`.

There is a security risk in not verifying certificates, but as only the headers are captured it is slight. Usually looking at the URL in a browser will reveal what the problem is (and it may well be machine-specific).

**Value**

A character vector with integer attribute "status" (the last-received 'status' code). If redirection occurs this will include the headers for all the URLs visited.

**See Also**

`capabilities("libcurl")` to see if this is supported. `libcurlVersion` for the version of libcurl in use.

`options` HTTPUserAgent and timeout are used.

**Examples**

```r
## needs Internet access, results vary
curlGetHeaders("http://bugs.r-project.org")  ## this redirects to https://
curlGetHeaders("https://httpbin.org/status/404")  ## returns status
curlGetHeaders("ftp://cran.r-project.org")
```

### cut

**Convert Numeric to Factor**

**Description**

cut divides the range of `x` into intervals and codes the values in `x` according to which interval they fall. The leftmost interval corresponds to level one, the next leftmost to level two and so on.

**Usage**

```r
cut(x, ...)
```

**Arguments**

- `x`: a numeric vector which is to be converted to a factor by cutting.
- `breaks`: either a numeric vector of two or more unique cut points or a single number (greater than or equal to 2) giving the number of intervals into which `x` is to be cut.
labels labels for the levels of the resulting category. By default, labels are constructed using "(a,b]" interval notation. If labels = FALSE, simple integer codes are returned instead of a factor.

include.lowest logical, indicating if an 'x[i]' equal to the lowest (or highest, for right = FALSE) 'breaks' value should be included.

right logical, indicating if the intervals should be closed on the right (and open on the left) or vice versa.

dig.lab integer which is used when labels are not given. It determines the number of digits used in formatting the break numbers.

ordered_result logical: should the result be an ordered factor?

... further arguments passed to or from other methods.

Details

When breaks is specified as a single number, the range of the data is divided into breaks pieces of equal length, and then the outer limits are moved away by 0.1% of the range to ensure that the extreme values both fall within the break intervals. (If x is a constant vector, equal-length intervals are created, one of which includes the single value.)

If a labels parameter is specified, its values are used to name the factor levels. If none is specified, the factor level labels are constructed as "(b1,b2]", "(b2,b3]" etc. for right = TRUE and as "[b1,b2)", ... if right = FALSE. In this case, dig.lab indicates the minimum number of digits should be used in formatting the numbers b1, b2, .... A larger value (up to 12) will be used if needed to distinguish between any pair of endpoints: if this fails labels such as "Range3" will be used. Formatting is done by formatC.

The default method will sort a numeric vector of breaks, but other methods are not required to and labels will correspond to the intervals after sorting.

As from R 3.2.0, getOption("OutDec") is consulted when labels are constructed for labels = NULL.

Value

A factor is returned, unless labels = FALSE which results in an integer vector of level codes.

Values which fall outside the range of breaks are coded as NA, as are NaN and NA values.

Note

Instead of table(cut(x,br)), hist(x,br,plot = FALSE) is more efficient and less memory hungry. Instead of cut(*,labels = FALSE), findInterval() is more efficient.

### some values OUTSIDE the breaks :
table(cx <- cut(x, breaks = 2*(0:4)))
table(cxl <- cut(x, breaks = 2*(0:4), right = FALSE))
which(is.na(cx)); x[is.na(cx)] #-- the first 9 values 0
which(is.na(cxl)); x[is.na(cxl)] #-- the last 5 values 8

## Label construction:
y <- stats::rnorm(100)
table(cut(y, breaks = pi/3*(-3:3)))
table(cut(y, breaks = pi/3*(-3:3), dig.lab = 4))

## extra digits don't "harm" here
table(cut(y, breaks = 1*(-3:3), right = FALSE))
#- the same, since no exact INT!

## sometimes the default dig.lab is not enough to be avoid confusion:
aaa <- c(1,2,3,4,5,2,3,4,5,6,7)
cut(aaa, 3)
cut(aaa, 3, dig.lab = 4, ordered = TRUE)

## one way to extract the breakpoints
labs <- levels(cut(aaa, 3))
cbind(lower = as.numeric( sub("\((.+),.*", "\1", labs) ),
       upper = as.numeric( sub("[^-],[^\[]],[^\[]]\", "\1", labs) ))

cut.POSIXt

Convert a Date or Date-Time Object to a Factor

Description

Method for cut applied to date-time objects.

Usage

### S3 method for class 'POSIXt'
cut(x, breaks, labels = NULL, start.on.monday = TRUE, right = FALSE, ...)

---

**Examples**

```r
Z <- stats::rnorm(10000)
table(cut(Z, breaks = -6:6))
sum(table(cut(Z, breaks = -6:6, labels = FALSE)))
sum(graphics::hist(Z, breaks = -6:6, plot = FALSE)$counts)

cut(rep(1,5), 4) #-- dummy
tx0 <- c(9, 4, 6, 5, 3, 10, 5, 3, 5)
x <- rep(0:8, tx0)
stopifnot(table(x) == tx0)

table( cut(x, b = 8))
table( cut(x, breaks = 3*(-2:5)))
table( cut(x, breaks = 3*(-2:5), right = FALSE))

### some values OUTSIDE the breaks :
table(cx <- cut(x, breaks = 2*(0:4)))
table(cxl <- cut(x, breaks = 2*(0:4), right = FALSE))
which(is.na(cx)); x[is.na(cx)] #-- the first 9 values 0
which(is.na(cxl)); x[is.na(cxl)] #-- the last 5 values 8

## Label construction:
y <- stats::rnorm(100)
table(cut(y, breaks = pi/3*(-3:3)))
table(cut(y, breaks = pi/3*(-3:3), dig.lab = 4))

## extra digits don't "harm" here
table(cut(y, breaks = 1*(-3:3), right = FALSE))
#- the same, since no exact INT!

## sometimes the default dig.lab is not enough to be avoid confusion:
aaa <- c(1,2,3,4,5,2,3,4,5,6,7)
cut(aaa, 3)
cut(aaa, 3, dig.lab = 4, ordered = TRUE)

## one way to extract the breakpoints
labs <- levels(cut(aaa, 3))
cbind(lower = as.numeric( sub("\((.+),.*", "\1", labs) ),
       upper = as.numeric( sub("[^-],[^\[]],[^\[]]\", "\1", labs) ))
```

**Description**

Method for cut applied to date-time objects.

**Usage**

### S3 method for class 'POSIXt'
cut(x, breaks, labels = NULL, start.on.monday = TRUE, right = FALSE, ...)

## S3 method for class 'Date'
cut(x, breaks, labels = NULL, start.on.monday = TRUE,
    right = FALSE, ...)

**Arguments**

- **x**: an object inheriting from class "POSIXt" or "Date".
- **breaks**: a vector of cut points or number giving the number of intervals which x is to be cut into or an interval specification, one of "sec", "min", "hour", "day", "DSTday", "week", "month", "quarter" or "year", optionally preceded by an integer and a space, or followed by "s". (For "Date" objects only interval specifications using "day", "week", "month", "quarter" and "year" are allowed.)
- **labels**: labels for the levels of the resulting category. By default, labels are constructed from the left-hand end of the intervals (which are included for the default value of `right`). If `labels = FALSE`, simple integer codes are returned instead of a factor.
- **start.on.monday**: logical. If `breaks = "weeks"`, should the week start on Mondays or Sundays?
- **right**, ...: arguments to be passed to or from other methods.

**Details**

Note that the default for `right` differs from the default method. Using `include.lowest = TRUE` will include both ends of the range of dates.

Using `breaks = "quarter"` will create intervals of 3 calendar months, with the intervals beginning on January 1, April 1, July 1 or October 1 (based upon `min(x)`) as appropriate.

A vector of `breaks` will be sorted before use: `labels` should correspond to the sorted vector.

**Value**

A factor is returned, unless `labels = FALSE` which returns the integer level codes.

Values which fall outside the range of `breaks` are coded as `NA`, as are and NA values.

**See Also**

seq.POSIXt, seq.Date, cut

**Examples**

```r
## random dates in a 10-week period
cut(ISOdate(2001, 1, 1) + 70*86400*stats::runif(100), "weeks")
cut(as.Date("2001/1/1") + 70*stats::runif(100), "weeks")

# The standards all have midnight as the start of the day, but some
# people incorrectly interpret it at the end of the previous day ...

tm <- seq.POSIXct("2012-06-01 06:00"), by = "6 hours", length.out = 24)
aggregate(1:24, list(day = cut(tm, "days")), mean)
# and a version with midnight included in the previous day:
aggregate(1:24, list(day = cut(tm, "days", right = TRUE)), mean)
```
data.class  

Object Classes

Description

Determine the class of an arbitrary R object.

Usage

data.class(x)

Arguments

x  
an R object.

Value

character string giving the class of x.

The class is the (first element) of the class attribute if this is non-NULL, or inferred from the object's 
dim attribute if this is non-NULL, or mode(x).

Simply speaking, data.class(x) returns what is typically useful for method dispatching. (Or, 
what the basic creator functions already and maybe eventually all will attach as a class attribute.)

Note

For compatibility reasons, there is one exception to the rule above: When x is integer, the result 
of data.class(x) is "numeric" even when x is classed.

See Also

class

Examples

x <- LETTERS
data.class(factor(x))  # has a class attribute
data.class(matrix(x, ncol = 13))  # has a dim attribute
data.class(list(x))  # the same as mode(x)
data.class(x)  # the same as mode(x)

stopifnot(data.class(1:2) == "numeric")  # compatibility "rule"
Description

The function `data.frame()` creates data frames, tightly coupled collections of variables which share many of the properties of matrices and of lists, used as the fundamental data structure by most of R’s modeling software.

Usage

```r
data.frame(..., row.names = NULL, check.rows = FALSE,
           check.names = TRUE, fix.empty.names = TRUE,
           stringsAsFactors = FALSE)
```

default.stringsAsFactors() # << this is deprecated!

Arguments

- `...` these arguments are of either the form `value` or `tag = value`. Component names are created based on the tag (if present) or the deparsed argument itself.
- `row.names` NULL or a single integer or character string specifying a column to be used as row names, or a character or integer vector giving the row names for the data frame.
- `check.rows` if `TRUE` then the rows are checked for consistency of length and names.
- `check.names` logical. If `TRUE` then the names of the variables in the data frame are checked to ensure that they are syntactically valid variable names and are not duplicated. If necessary they are adjusted (by `make.names`) so that they are.
- `fix.empty.names` logical indicating if arguments which are “unnamed” (in the sense of not being formally called as `someName = arg`) get an automatically constructed name or rather name “”. Needs to be set to `FALSE` even when `check.names` is false if “” names should be kept.
- `stringsAsFactors` logical: should character vectors be converted to factors? The ‘factory-fresh’ default has been `TRUE` previously but has been changed to `FALSE` for R 4.0.0.

Details

A data frame is a list of variables of the same number of rows with unique row names, given class "data.frame". If no variables are included, the row names determine the number of rows.

The column names should be non-empty, and attempts to use empty names will have unsupported results. Duplicate column names are allowed, but you need to use `check.names = FALSE` for `data.frame` to generate such a data frame. However, not all operations on data frames will preserve duplicated column names: for example matrix-like subsetting will force column names in the result to be unique.

`data.frame` converts each of its arguments to a data frame by calling `as.data.frame(optional = TRUE)`. As that is a generic function, methods can be written to change the behaviour of arguments according to their classes: R comes with many such methods. Character variables passed to
data.frame are converted to factor columns unless protected by I or argument stringsAsFactors is false. If a list or data frame or matrix is passed to data.frame it is as if each component or column had been passed as a separate argument (except for matrices protected by I).

Objects passed to data.frame should have the same number of rows, but atomic vectors (see is.vector), factors and character vectors protected by I will be recycled a whole number of times if necessary (including as elements of list arguments).

If row names are not supplied in the call to data.frame, the row names are taken from the first component that has suitable names, for example a named vector or a matrix with rownames or a data frame. (If that component is subsequently recycled, the names are discarded with a warning.) If row.names was supplied as NULL or no suitable component was found the row names are the integer sequence starting at one (and such row names are considered to be ‘automatic’, and not preserved by as.matrix).

If row names are supplied of length one and the data frame has a single row, the row.names is taken to specify the row names and not a column (by name or number).

Names are removed from vector inputs not protected by I.

default.stringsAsFactors is a utility that takes getOption("stringsAsFactors") and ensures the result is TRUE or FALSE (or throws an error if the value is not NULL). This function is deprecated now and will no longer be available in the future.

Value

A data frame, a matrix-like structure whose columns may be of differing types (numeric, logical, factor and character and so on).

How the names of the data frame are created is complex, and the rest of this paragraph is only the basic story. If the arguments are all named and simple objects (not lists, matrices of data frames) then the argument names give the column names. For an unnamed simple argument, a deparsed version of the argument is used as the name (with an enclosing I(...) removed). For a named matrix/list/data frame argument with more than one named column, the names of the columns are the name of the argument followed by a dot and the column name inside the argument: if the argument is unnamed, the argument's column names are used. For a named or unnamed matrix/list/data frame argument that contains a single column, the column name in the result is the column name in the argument. Finally, the names are adjusted to be unique and syntactically valid unless check.names = FALSE.

Note

In versions of R prior to 2.4.0 row.names had to be character: to ensure compatibility with such versions of R, supply a character vector as the row.names argument.

Examples

```r
L3 <- LETTERS[1:3]
fac <- sample(L3, 10, replace = TRUE)
(d <- data.frame(x = 1, y = 1:10, fac = fac))
## The "same" with automatic column names:
data.frame(1, 1:10, sample(L3, 10, replace = TRUE))

is.data.frame(d)

## do not convert to factor, using I() :
(dd <- cbind(d, char = I(letters[1:10])))
rbind(class = sapply(dd, class), mode = sapply(dd, mode))

stopifnot(1:10 == row.names(d)) # {coercion}
(d0 <-(d[, FALSE]) # data frame with 0 columns and 10 rows
(d.0 <- d[FALSE, ]) # <0 rows> data frame (3 named cols)
(d00 <- d0[FALSE, ]) # data frame with 0 columns and 0 rows
```

---

**data.matrix**

Convert a Data Frame to a Numeric Matrix

**Description**

Return the matrix obtained by converting all the variables in a data frame to numeric mode and then binding them together as the columns of a matrix. Factors and ordered factors are replaced by their internal codes.

**Usage**

```r
data.matrix(frame, rownames.force = NA)
```

**Arguments**

- `frame`: a data frame whose components are logical vectors, factors or numeric or character vectors.
- `rownames.force`: logical indicating if the resulting matrix should have character (rather than NULL) rownames. The default, NA, uses NULL rownames if the data frame has ‘automatic’ row.names or for a zero-row data frame.

**Details**

Logical and factor columns are converted to integers. Character columns are first converted to factors and then to integers. Any other column which is not numeric (according to `is.numeric`) is converted by `as.numeric` or, for S4 objects, `as("numeric")`. If all columns are integer (after conversion) the result is an integer matrix, otherwise a numeric (double) matrix.

**Value**

If `frame` inherits from class "data.frame", an integer or numeric matrix of the same dimensions as `frame`, with dimnames taken from the `row.names` (or NULL, depending on `rownames.force`) and names.

Otherwise, the result of `as.matrix`.
Note

The default behaviour for data frames differs from R < 2.5.0 which always gave the result character rownames.

Examples

```R
DF <- data.frame(a = 1:3, b = letters[10:12],
                 c = seq(as.Date("2004-01-01"), by = "week", len = 3),
                 stringsAsFactors = TRUE)
data.matrix(DF[1:2])
data.matrix(DF)
```

---

date | System Date and Time

Description

Returns a character string of the current system date and time.

Usage

date()

Value

The string has the form "Fri Aug 20 11:11:00 1999", i.e., length 24, since it relies on POSIX’s ctime ensuring the above fixed format. Timezone and Daylight Saving Time are taken account of, but not indicated in the result.

The day and month abbreviations are always in English, irrespective of locale.

References

Examples

(d <- date())
nchar(d) == 24

## something similar in the current locale
format(Sys.time(), "%a %b %d %H:%M:%S %Y")

---

Description  

Description of the class "Date" representing calendar dates.

Usage

## S3 method for class 'Date'
summary(object, digits = 12, ...)

## S3 method for class 'Date'
print(x, max = NULL, ...)

Arguments

object, x  
a Date object to be summarized or printed.
digits  
number of significant digits for the computations.
max  
umeric or NULL, specifying the maximal number of entries to be printed. By default, when NULL, `getOption("max.print")` used.

...  
further arguments to be passed from or to other methods.

Details

Dates are represented as the number of days since 1970-01-01, with negative values for earlier dates. They are always printed following the rules of the current Gregorian calendar, even though that calendar was not in use long ago (it was adopted in 1752 in Great Britain and its colonies). It is intended that the date should be an integer, but this is not enforced in the internal representation. Fractional days will be ignored when printing. It is possible to produce fractional days via the `mean` method or by adding or subtracting (see `Ops.Date`).

From the many methods, see `methods(class = "Date")`, a few are documented separately, see below.

See Also

`Sys.Date` for the current date.
`weekdays` for convenience extraction functions.
Methods with extra arguments and documentation:

`Ops.Date` for operators on "Date" objects.
format.Date for conversion to and from character strings.
axis.Date and hist.Date for plotting.
seq.Date, cut.Date, and round.Date for utility operations.

DateTimeClasses for date-time classes.

Examples

(today <- Sys.Date())
format(today, "%d %b %Y") # with month as a word
(tenweeks <- seq(today, length.out=10, by="1 week")(next ten weeks
weekdays(today)
months(tenweeks)

(Dls <- as.Date(.leap.seconds))

## length(<Date>) <- n now works
ls <- Dls; length(ls) <- 12
l2 <- Dls; length(l2) <- 5 + length(Dls)
stopifnot(exprs = {
  ## length(.) <- * is compatible to subsetting/indexing:
  identical(ls, Dls[seq_along(ls)])
  identical(l2, Dls[seq_along(l2)])
  ## has filled with NA's
  is.na(l2[(length(Dls)+1):length(l2)])
})

DateTimeClasses        Date-Time Classes

Description

Description of the classes "POSIXlt" and "POSIXct" representing calendar dates and times.

Usage

## S3 method for class 'POSIXct'
print(x, tz = "", usetz = TRUE, max = NULL, ...)

## S3 method for class 'POSIXct'
summary(object, digits = 15, ...)

time + z
z + time
time - z
time1 lop time2

Arguments

x, object an object to be printed or summarized from one of the date-time classes.
tz, usetz for timezone formatting, passed to format.POSIXct.
max numeric or NULL, specifying the maximal number of entries to be printed. By
default, when NULL, getOption("max.print") used.
DateTimeClasses

digits

number of significant digits for the computations: should be high enough to represent the least important time unit exactly.

... further arguments to be passed from or to other methods.

time
date-time objects
time1, time2
date-time objects or character vectors. (Character vectors are converted by as.POSIXct.)

z

a numeric vector (in seconds)

lop

one of ==, !=, <, <=, > or >=.

Details

There are two basic classes of date/times. Class "POSIXct" represents the (signed) number of seconds since the beginning of 1970 (in the UTC time zone) as a numeric vector. Class "POSIXlt" is a named list of vectors representing

- sec 0–61: seconds.
- min 0–59: minutes.
- hour 0–23: hours.
- mday 1–31: day of the month
- mon 0–11: months after the first of the year.
- year years since 1900.
- wday 0–6 day of the week, starting on Sunday.
- yday 0–365: day of the year (365 only in leap years).
- isdst Daylight Saving Time flag. Positive if in force, zero if not, negative if unknown.
- zone (Optional.) The abbreviation for the time zone in force at that time: "" if unknown (but "" might also be used for UTC).
- gmtoff (Optional.) The offset in seconds from GMT: positive values are East of the meridian. Usually NA if unknown, but 0 could mean unknown.

(The last two components are not present for times in UTC and are platform-dependent: they are supported on platforms based on BSD or glibc (including Linux and macOS) and those using the tzcode implementation shipped with R (including Windows). But they are not necessarily set.)

Note that the internal list structure is somewhat hidden, as many methods (including length(x), print() and str) apply to the abstract date-time vector, as for "POSIXct". As from R 3.5.0, one can extract and replace single components via [ indexing with two indices (see the examples). The classes correspond to the POSIX/C99 constructs of 'calendar time' (the time_t data type) and 'local time' (or broken-down time, the struct tm data type), from which they also inherit their names. The components of "POSIXlt" are integer vectors, except sec and zone.

"POSIXct" is more convenient for including in data frames, and "POSIXlt" is closer to human-readable forms. A virtual class "POSIXlt" exists from which both of the classes inherit: it is used to allow operations such as subtraction to mix the two classes.

Components wday and yday of "POSIXlt" are for information, and are not used in the conversion to calendar time. However, isdst is needed to distinguish times at the end of DST: typically 1am to 2am occurs twice, first in DST and then in standard time. At all other times isdst can be deduced from the first six values, but the behaviour if it is set incorrectly is platform-dependent.

Logical comparisons and some arithmetic operations are available for both classes. One can add or subtract a number of seconds from a date-time object, but not add two date-time objects. Subtraction of two date-time objects is equivalent to using difftime. Be aware that "POSIXlt" objects will
be interpreted as being in the current time zone for these operations unless a time zone has been specified.

"POSIXlt" objects will often have an attribute "tzone", a character vector of length 3 giving the time zone name (from the TZ environment variable or argument tz of functions creating "POSIXlt" objects; "" marks the current time zone) and the names of the base time zone and the alternate (daylight-saving) time zone. Sometimes this may just be of length one, giving the time zone name.

"POSIXct" objects may also have an attribute "tzone", a character vector of length one. If set to a non-empty value, it will determine how the object is converted to class "POSIXlt" and in particular how it is printed. This is usually desirable, but if you want to specify an object in a particular time zone but to be printed in the current time zone you may want to remove the "tzone" attribute (e.g., by c(x)).

Unfortunately, the conversion is complicated by the operation of time zones and leap seconds (according to this version of R's data, 27 days have been 86401 seconds long so far, the last being on (actually, immediately before) 2017-01-01: the times of the extra seconds are in the object .leap.seconds). The details of this are entrusted to the OS services where possible. It seems that some rare systems used to use leap seconds, but all known current platforms ignore them (as required by POSIX). This is detected and corrected for at build time, so "POSIXct" times used by R do not include leap seconds on any platform.

Using c on "POSIXlt" objects converts them to the current time zone, and on "POSIXct" objects drops any "tzone" attributes, unless they are all marked with the same time zone.

A few times have specific issues. First, the leap seconds are ignored, and real times such as "2005-12-31 23:59:60" are (probably) treated as the next second. However, they will never be generated by R, and are unlikely to arise as input. Second, on some OSes there is a problem in the POSIX/C99 standard with "1969-12-31 23:59:59 UTC", which is -1 in calendar time and that value is on those OSes also used as an error code. Thus as.POSIXct("1969-12-31 23:59:59",format = "%Y-%m-%d %H:%M:%S",tz = "UTC") may give NA, and hence as.POSIXct("1969-12-31 23:59:59",tz = "UTC") will give "1969-12-31 23:59:00". Other OSes (including the code used by R on Windows) report errors separately and so are able to handle that time as valid.

The print methods respect options("max.print").

Sub-second Accuracy

Classes "POSIXct" and "POSIXlt" are able to express fractions of a second. (Conversion of fractions between the two forms may not be exact, but will have better than microsecond accuracy.)

Fractional seconds are printed only if options("digits.secs") is set: see strftime.

Valid ranges for times

The "POSIXlt" class can represent a very wide range of times (up to billions of years), but such times can only be interpreted with reference to a time zone.

The concept of time zones was first adopted in the nineteenth century, and the Gregorian calendar was introduced in 1582 but not universally adopted until 1927. OS services almost invariably assume the Gregorian calendar and may assume that the time zone that was first enacted for the location was in force before that date. (The earliest legislated time zone seems to have been London on 1847-12-01.) Some OSes assume the previous use of 'local time' based on the longitude of a location within the time zone.

Most operating systems represent POSIXct times as C type long. This means that on 32-bit OSes this covers the period 1902 to 2037. On all known 64-bit platforms and for the code we use on 32-bit Windows, the range of representable times is billions of years: however, not all can convert
correctly times before 1902 or after 2037. A few benighted OSes used a unsigned type and so cannot represent times before 1970.

Where possible the platform limits are detected, and outside the limits we use our own C code. This uses the offset from GMT in use either for 1902 (when there was no DST) or that predicted for one of 2030 to 2037 (chosen so that the likely DST transition days are Sundays), and uses the alternate (daylight-saving) time zone only if isdst is positive or (if -1) if DST was predicted to be in operation in the 2030s on that day.

Note that there are places (e.g., Rome) whose offset from UTC varied in the years prior to 1902, and these will be handled correctly only where there is OS support.

There is no reason to suppose that the DST rules will remain the same in the future, and indeed the US legislated in 2005 to change its rules as from 2007, with a possible future reversion. So conversions for times more than a year or two ahead are speculative.

**Warnings**

Some Unix-like systems (especially Linux ones) do not have environment variable `TZ` set, yet have internal code that expects it (as does POSIX). We have tried to work around this, but if you get unexpected results try setting `TZ`. See `Sys.timezone` for valid settings.

Great care is needed when comparing objects of class "POSIXlt". Not only are components and attributes optional; several components may have values meaning ‘not yet determined’ and the same time represented in different time zones will look quite different.

Currently the order of the list components of "POSIXlt" objects must not be changed, as several C-based conversion methods rely on the order for efficiency.

**References**

**See Also**

`Dates` for dates without times.

`as.POSIXct` and `as.POSIXlt` for conversion between the classes.

`strptime` for conversion to and from character representations.

`Sys.time` for clock time as a "POSIXct" object.

`difftime` for time intervals.

`cut.POSIXt`, `seq.POSIXt`, `round.POSIXt` and `trunc.POSIXt` for methods for these classes.

`weekdays` for convenience extraction functions.

**Examples**

```r
(z <- Sys.time()) # the current date, as class "POSIXct"
Sys.time() - 3600 # an hour ago
as.POSIXlt(Sys.time(), "GMT") # the current time in GMT
format(.leap.seconds) # the leap seconds in your time zone
print(.leap.seconds, tz = "PST8PDT") # and in Seattle's
```

## look at *internal* representation of "POSIXlt":

```r
```
leapS <- as.POSIXlt(.leap.seconds)
names(leapS) ; is.list(leapS)
## str() "too smart" --> need unclass(.):
utils::str(unclass(leapS), vec.len = 7)
## Extracting *single* components of POSIXlt objects:
leapS[1 : 5, "year"]

## length(.) <- n now works for "POSIXct" and "POSIXlt" :
for(lpS in list(.leap.seconds, leapS)) {
  1s <- lpS; length(1s) <- 12
  l2 <- lpS; length(l2) <- 5 + length(lpS)
  stopifnot(exprs = {
    ## length(.) <- * is compatible to subsetting/indexing:
    identical(1s, lpS[seq_along(1s)])
    identical(l2, lpS[seq_along(l2)])
    ## has filled with NA's
    is.na(l2[(length(lpS)+1):length(l2)])
  })
}

dcf

# Read and Write Data in DCF Format

**Description**

Reads or writes an R object from/to a file in Debian Control File format.

**Usage**

```r
read.dcf(file, fields = NULL, all = FALSE, keep.white = NULL)
write.dcf(x, file = "", append = FALSE, useBytes = FALSE,
         indent = 0.1 * getOption("width"),
         width = 0.9 * getOption("width"),
         keep.white = NULL)
```

**Arguments**

- `file` either a character string naming a file or a `connection`. "" indicates output to the console. For `read.dcf` this can name a compressed file (see `gzfile`).
- `fields` Fields to read from the DCF file. Default is to read all fields.
- `all` a logical indicating whether in case of multiple occurrences of a field in a record, all these should be gathered. If `all` is false (default), only the last such occurrence is used.
- `keep.white` a character string with the names of the fields for which whitespace should be kept as is, or `NULL` (default) indicating that there are no such fields. Coerced to character if possible. For fields where whitespace is not to be kept as is, `read.dcf` removes leading and trailing whitespace, and `write.dcf` folds using `strwrap`.
- `x` the object to be written, typically a data frame. If not, it is attempted to coerce `x` to a data frame.
append: logical. If TRUE, the output is appended to the file. If FALSE, any existing file of the name is destroyed.

useBytes: logical to be passed to writeLines(), see there: “for expert use”.

indent: a positive integer specifying the indentation for continuation lines in output entries.

width: a positive integer giving the target column for wrapping lines in the output.

Details

DCF is a simple format for storing databases in plain text files that can easily be directly read and written by humans. DCF is used in various places to store R system information, like descriptions and contents of packages.

The DCF rules as implemented in R are:

1. A database consists of one or more records, each with one or more named fields. Not every record must contain each field. Fields may appear more than once in a record.
2. Regular lines start with a non-whitespace character.
3. Regular lines are of form tag:value, i.e., have a name tag and a value for the field, separated by : (only the first counts). The value can be empty (i.e., whitespace only).
4. Lines starting with whitespace are continuation lines (to the preceding field) if at least one character in the line is non-whitespace. Continuation lines where the only non-whitespace character is a ‘.’ are taken as blank lines (allowing for multi-paragraph field values).
5. Records are separated by one or more empty (i.e., whitespace only) lines.
6. Individual lines may not be arbitrarily long; prior to R 3.0.2 the length limit was approximately 8191 bytes per line.

Note that read.dcf(all = FALSE) reads the file byte-by-byte. This allows a ‘DESCRIPTION’ file to be read and only its ASCII fields used, or its ‘Encoding’ field used to re-encode the remaining fields.

write.dcf does not write NA fields.

Value

The default read.dcf(all = FALSE) returns a character matrix with one row per record and one column per field. Leading and trailing whitespace of field values is ignored unless a field is listed in keep.white. If a tag name is specified in the file, but the corresponding value is empty, then an empty string is returned. If the tag name of a field is specified in fields but never used in a record, then the corresponding value is NA. If fields are repeated within a record, the last one encountered is returned. Malformed lines lead to an error.

For read.dcf(all = TRUE) a data frame is returned, again with one row per record and one column per field. The columns are lists of character vectors for fields with multiple occurrences, and character vectors otherwise.

Note that an empty file is a valid DCF file, and read.dcf will return a zero-row matrix or data frame.

For write.dcf, invisible NULL.

Note

As from R 3.4.0, ‘whitespace’ in all cases includes newlines.
debug

References

Note that R does not require encoding in UTF-8, which is a recent Debian requirement. Nor does it use the Debian-specific sub-format which allows comment lines starting with ‘#’.

See Also

write.table, available.packages, which uses read.dcf to read the indices of package repositories.

Examples

```r
## Create a reduced version of the DESCRIPTION file in package 'splines'
x <- read.dcf(file = system.file("DESCRIPTION", package = "splines"),
               fields = c("Package", "Version", "Title"))
write.dcf(x)

## An online DCF file with multiple records
con <- url("https://cran.r-project.org/src/contrib/PACKAGES")
y <- read.dcf(con, all = TRUE)
close(con)
utils::str(y)
```

---

debug

Debug a Function

Description

Set, unset or query the debugging flag on a function. The text and condition arguments are the same as those that can be supplied via a call to browser. They can be retrieved by the user once the browser has been entered, and provide a mechanism to allow users to identify which breakpoint has been activated.

Usage

```r
debug(fun, text = "", condition = NULL, signature = NULL)
debugonce(fun, text = "", condition = NULL, signature = NULL)
undebug(fun, signature = NULL)
isdebugged(fun, signature = NULL)
debuggingState(on = NULL)
```

Arguments

- `fun`: any interpreted R function.
- `text`: a text string that can be retrieved when the browser is entered.
- `condition`: a condition that can be retrieved when the browser is entered.
- `signature`: an optional method signature. If specified, the method is debugged, rather than its generic.
debug

logical; a call to the support function debuggingState returns TRUE if debugging is globally turned on, FALSE otherwise. An argument of one or the other of those values sets the state. If the debugging state is FALSE, none of the debugging actions will occur (but explicit browser calls in functions will continue to work).

Details

When a function flagged for debugging is entered, normal execution is suspended and the body of function is executed one statement at a time. A new browser context is initiated for each step (and the previous one destroyed).

At the debug prompt the user can enter commands or R expressions, followed by a newline. The commands are described in the browser help topic.

To debug a function which is defined inside another function, single-step through to the end of its definition, and then call debug on its name.

If you want to debug a function not starting at the very beginning, use trace(.,at = *) or setBreakpoint.

Using debug is persistent, and unless debugging is turned off the debugger will be entered on every invocation (note that if the function is removed and replaced the debug state is not preserved). Use debugonce() to enter the debugger only the next time the function is invoked.

To debug an S4 method by explicit signature, use signature. When specified, signature indicates the method of fun to be debugged. Note that debugging is implemented slightly differently for this case, as it uses the trace machinery, rather than the debugging bit. As such, text and condition cannot be specified in combination with a non-null signature. For methods which implement the .local rematching mechanism, the .local closure itself is the one that will be ultimately debugged (see isRematched).

isdebugged returns TRUE if a) signature is NULL and the closure fun has been debugged, or b) signature is not NULL, fun is an S4 generic, and the method of fun for that signature has been debugged. In all other cases, it returns FALSE.

The number of lines printed for the deparsed call when a function is entered for debugging can be limited by setting options(deparse.max.lines).

When debugging is enabled on a byte compiled function then the interpreted version of the function will be used until debugging is disabled.

Value

d debug and undebug invisibly return NULL.

isdebugged returns TRUE if the function or method is marked for debugging, and FALSE otherwise.

See Also

Examples

## Not run:
d debug(library)
library(methods)
Defunct

Marking Objects as Defunct

Description

When a function is removed from R it should be replaced by a function which calls .Defunct.

Usage

```
.Defunct(new, package = NULL, msg)
```

Arguments

- `new`: character string: A suggestion for a replacement function.
- `package`: character string: The package to be used when suggesting where the defunct function might be listed.
- `msg`: character string: A message to be printed, if missing a default message is used.

Details

`.Defunct` is called from `defunct` functions. Functions should be listed in `help("pkg-defunct")` for an appropriate pkg, including `base` (with the alias added to the respective Rd file).

`.Defunct` signals an error of class `defunctError` with fields `old`, `new`, and `package`.

See Also

- `Deprecated`
- `base-defunct` and so on which list the defunct functions in the packages.
**delayedAssign**

**Delay Evaluation**

**Description**

`delayedAssign` creates a *promise* to evaluate the given expression if its value is requested. This provides direct access to the lazy evaluation mechanism used by R for the evaluation of (interpreted) functions.

**Usage**

```r
delayedAssign(x, value, eval.env = parent.frame(1),
             assign.env = parent.frame(1))
```

**Arguments**

- `x` a variable name (given as a quoted string in the function call)
- `value` an expression to be assigned to `x`
- `eval.env` an environment in which to evaluate `value`
- `assign.env` an environment in which to assign `x`

**Details**

Both `eval.env` and `assign.env` default to the currently active environment.

The expression assigned to a promise by `delayedAssign` will not be evaluated until it is eventually 'forced'. This happens when the variable is first accessed.

When the promise is eventually forced, it is evaluated within the environment specified by `eval.env` (whose contents may have changed in the meantime). After that, the value is fixed and the expression will not be evaluated again.

**Value**

This function is invoked for its side effect, which is assigning a promise to evaluate `value` to the variable `x`.

**See Also**

`substitute`, to see the expression associated with a promise, if `assign.env` is not the `.GlobalEnv`.

**Examples**

```r
msg <- "old"
donkey("x", msg)
substitute(x) # shows only 'x', as it is in the global env.
msg <- "new!"
x # new!

delayedAssign("x", {
    for(i in 1:3)
        cat("yippee!\n")
})
```
deparse

### Promises in an environment [for advanced users]:  ---------------------

```r
e <- (function(x, y = 1, z) environment())(cos, "y", (cat(" HO!
\n"); pi+2))
```

```r
## How can we look at all promises in an env (w/o forcing them)?
gete <- function(e_)
  lapply(lapply(ls(e_), as.name),
    function(n) eval(substitute(substitute(X, e_), list(X=n)))))

(exps <- gete(e))
sapply(exps, typeof)
```

```r
(lle <- as.list(e)) # evaluates ("force"s) the promises
```

```r
stopifnot(identical(unname(lle), lapply(exps, eval))) # and another "Ho!"
```

---

deparse  

*Expression Deparsing*

---

**Description**

Turn unevaluated expressions into character strings.

**Usage**

```r
deparse(expr, width.cutoff = 60L,
  backtick = mode(expr) %in% c("call", "expression", "("", "function"),
  control = c("keepNA", "keepInteger", "niceNames", "showAttributes"),
  nlines = -1L)
```

```r
deparse1(expr, collapse = " ", width.cutoff = 500L, ...)
```

**Arguments**

- **expr**: any R expression.
- **width.cutoff**: integer in \([20, 500]\) determining the cutoff (in bytes) at which line-breaking is tried.
- **backtick**: logical indicating whether symbolic names should be enclosed in backticks if they do not follow the standard syntax.
- **control**: character vector (or NULL) of deparsing options. See `.deparseOpts`.
- **nlines**: integer: the maximum number of lines to produce. Negative values indicate no limit.
- **collapse**: a string, passed to `paste()`.
- **...**: further arguments passed to `deparse()`.
Details

These functions turn unevaluated expressions (where ‘expression’ is taken in a wider sense than
the strict concept of a vector of mode and type (typeof) "expression" used in expression) into
character strings (a kind of inverse to parse).

A typical use of this is to create informative labels for data sets and plots. The example shows a
simple use of this facility. It uses the functions deparse and substitute to create labels for a plot
which are character string versions of the actual arguments to the function myplot.

The default for the backtick option is not to quote single symbols but only composite expressions.
This is a compromise to avoid breaking existing code.

Using control = c("all","hexDigits") comes closest to making deparse() an inverse of
parse() (but we have not yet seen an example where "all", now including "digits17", would
not have been as good). However, not all objects are deparse-able even with these options and a
warning will be issued if the function recognizes that it is being asked to do the impossible.

Unless control contains "digits17" or "hexDigits", (or "all" or "exact" which include one
of these), numeric and complex vectors are converted using 15 significant digits: see as.character
for more details.

width.cutoff is a lower bound for the line lengths: deparsing a line proceeds until at least
width.cutoff bytes have been output and e.g. arg = value expressions will not be split across
lines.

deparse1() is a simple utility added in R 4.0.0 to ensure a string result (character
vector of length one), typically used in name construction, as deparse1(substitute(.)).

Note

To avoid the risk of a source attribute out of sync with the actual function definition, the source
attribute of a function will never be deparsed as an attribute.

Deparsing internal structures may not be accurate: for example the graphics display list recorded by
recordPlot is not intended to be deparsed and .Internal calls will be shown as primitive calls.

References

Brooks/Cole.

See Also

.deparseOpts for available control settings; dput() and dump() for related functions using identi-
tical internal deparsing functionality.

substitute, parse, expression.

Quotes for quoting conventions, including backticks.

Examples

require(stats); require(graphics)

deparse(args(lm))
deparse(args(lm), width = 500)

myplot <- function(x, y) {
  plot(x, y, xlab = deparse1(substitute(x)),
       ylab = deparse1(substitute(y)))
}

```r
e <- quote(`foo bar`) deparse(e) deparse(e, backtick = TRUE) e <- quote(`foo bar`+1) deparse(e) deparse(e, control = "all") # wraps it w/ quote(.)
```

---

### Description

Process the deparsing options for `deparse`, `dput` and `dump`.

### Usage

```r
..deparseOpts(control)
```

### Arguments

- **control** character vector of deparsing options.

### Details

..deparseOpts is the character vector of possible deparsing options used by ..deparseOpts(). ..deparseOpts() is called by `deparse`, `dput` and `dump` to process their control argument. The control argument is a vector containing zero or more of the following strings (exactly those in ..deparseOpts). Partial string matching is used.

- **"keepInteger"**: Either surround integer vectors by `as.integer()` or use suffix L, so they are not converted to type double when parsed. This includes making sure that integer NAs are preserved (via `NA_integer_` if there are no non-NA values in the vector, unless "S_compatible" is set).

- **"quoteExpressions"**: Surround unevaluated expressions, but not formulas, with `quote()`, so they are not evaluated when re-parsed.

- **"showAttributes"**: If the object has attributes (other than a source attribute, see `srcref`), use `structure()` to display them as well as the object value unless the only such attribute is `names` and the "niceNames" option is set. This ("showAttributes") is the default for `deparse` and `dput`.

- **"useSource"**: If the object has a source attribute (`srcref`), display that instead of deparsing the object. Currently only applies to function definitions.

- **"warnIncomplete"**: Some exotic objects such as environments, external pointers, etc. can not be deparsed properly. This option causes a warning to be issued if the deparser recognizes one of these situations. Also, the parser in R < 2.7.0 would only accept strings of up to 8192 bytes, and this option gives a warning for longer strings.
"keepNA": Integer, real and character NAs are surrounded by coercion functions where necessary to ensure that they are parsed to the same type. Since e.g. `NA_real_` can be output in R, this is mainly used in connection with S-compatible.

"niceNames": If true, lists and atomic vectors with non-NA names (see names) are deparsed as e.g., `c(A = 1)` instead of `structure(1, Names = "A")`, independently of the "showAttributes" setting.

"all": An abbreviated way to specify all of the options listed above plus "digits17" (since R version 4.0.0). This is the default for dump, and, without "digits17", the options used by edit (which are fixed).

"delayPromises": Deparse promises in the form <promise: expression> rather than evaluating them. The value and the environment of the promise will not be shown and the deparsed code cannot be sourced.

"S_compatible": Make deparsing as far as possible compatible with S and R < 2.5.0. For compatibility with S, integer values of double vectors are deparsed with a trailing decimal point. Backticks are not used.

"hexNumeric": Real and finite complex numbers are output in "%a" format as binary fractions (coded as hexadecimal: see sprintf) with maximal opportunity to be recorded exactly to full precision. Complex numbers with one or both non-finite components are output as if this option were not set. (This relies on that format being correctly supported: known problems on Windows are worked around as from R 3.1.2.)

"digits17": Real and finite complex numbers are output using format "%g", which may give more precision than the default (but the output will depend on the platform and there may be loss of precision when read back). Complex numbers with one or both non-finite components are output as if this option were not set.

"exact": An abbreviated way to specify control = c("all","hexNumeric") which is guaranteed to be exact for numbers, see also below.

For the most readable (but perhaps incomplete) display, use control = NULL. This displays the object’s value, but not its attributes. The default in deparse is to display the attributes as well, but not to use any of the other options to make the result parseable. (dput and dump do use more default options, and printing of functions without sources uses c("keepInteger","keepNA").)

Using control = c("all","hexNumeric") comes closest to making deparse() an inverse of parse(), as representing double and complex numbers as decimals may well not be exact. However, not all objects are deparse-able even with this option. A warning will be issued if the function recognizes that it is being asked to do the impossible.

Only one of "hexNumeric" and "digits17" can be specified.

**Value**

An integer value corresponding to the control options selected.

**Examples**

(iOpt.all <- .deparseOpts("all")) # a four digit integer

## one integer --> vector binary bits
int2bits <- function(x, base = 2L, 
  ndigits = 1 + floor(1e-9 + log(max(x,1), base))) {
  r <- numeric(ndigits)
  for (i in ndigits:1) {
    r[i] <- x[i] %% base
    x[i] <- x[i] %/% base
r[i] <- x%%base
if (i > 1L)
  x <- x%%base
}
rev(r) # smallest bit at left
}
int2bits(iOpt.all)
## what options does "all" contain?
dep0.indiv <- setdiff(.deparseOpts, c("all", "exact"))
(oa <- dep0.indiv[int2bits(iOpt.all) == 1])
stopifnot(identical(iOpt.all, .deparseOpts(oa)))
## ditto for "exact" instead of "all":
int2bits(iOpt.X) <- .deparseOpts("exact")
(oX <- dep0.indiv[int2bits(iOpt.X) == 1])
diffXall <- oa != oX
stopifnot(identical(iOpt.X, .deparseOpts(oX)),
  identical(oX[diffXall], "hexNumeric"),
  identical(oa[diffXall], "digits17")

---

**Deprecated**

**Marking Objects as Deprecated**

**Description**

When an object is about to be removed from R it is first deprecated and should include a call to `.Deprecated`.

**Usage**

`.Deprecated(new, package=NULL, msg, old = as.character(sys.call(sys.parent()))[1L])`

**Arguments**

- `new` character string: A suggestion for a replacement function.
- `package` character string: The package to be used when suggesting where the deprecated function might be listed.
- `msg` character string: A message to be printed, if missing a default message is used.
- `old` character string specifying the function (default) or usage which is being deprecated.

**Details**

`.Deprecated("<new name>")` is called from deprecated functions. The original help page for these functions is often available at `help("oldName-deprecated")` (note the quotes). Functions should be listed in `help("pkg-deprecated")` for an appropriate `pkg`, including `base`.

`.Deprecated` signals a warning of class `deprecatedWarning` with fields `old`, `new`, and `package`.

**See Also**

`Defunct`

base-deprecated and so on which list the deprecated functions in the packages.
**Description**

det calculates the determinant of a matrix. determinant is a generic function that returns separately the modulus of the determinant, optionally on the logarithm scale, and the sign of the determinant.

**Usage**

det(x, 

```r
det(x, ...) determinant(x, logarithm = TRUE, ...)
```

**Arguments**

- **x**: numeric matrix: logical matrices are coerced to numeric.
- **logarithm**: logical; if TRUE (default) return the logarithm of the modulus of the determinant.
- **...**: Optional arguments. At present none are used. Previous versions of det allowed an optional method argument. This argument will be ignored but will not produce an error.

**Details**

The determinant function uses an LU decomposition and the det function is simply a wrapper around a call to determinant.

Often, computing the determinant is not what you should be doing to solve a given problem.

**Value**

For det, the determinant of x. For determinant, a list with components

- **modulus**: a numeric value. The modulus (absolute value) of the determinant if logarithm is FALSE; otherwise the logarithm of the modulus.
- **sign**: integer; either +1 or −1 according to whether the determinant is positive or negative.

**Examples**

```r
(x <- matrix(1:4, ncol = 2)) unlist(determinant(x)) det(x) det(print(cbind(1, 1:3, c(2,0,1))))
```
**Description**

Detach a database, i.e., remove it from the `search()` path of available R objects. Usually this is either a `data.frame` which has been `attach`ed or a package which was attached by `library`.

**Usage**

```r
detach(name, pos = 2L, unload = FALSE, character.only = FALSE, force = FALSE)
```

**Arguments**

- **name**: The object to detach. Defaults to `search()[pos]`. This can be an unquoted name or a character string but not a character vector. If a number is supplied this is taken as `pos`.
- **pos**: Index position in `search()` of the database to detach. When `name` is a number, `pos = name` is used.
- **unload**: A logical value indicating whether or not to attempt to unload the namespace when a package is being detached. If the package has a namespace and `unload` is `TRUE`, then `detach` will attempt to unload the namespace via `unloadNamespace`: if the namespace is imported by another namespace or `unload` is `FALSE`, no unloading will occur.
- **character.only**: A logical indicating whether `name` can be assumed to be a character string.
- **force**: Logical: should a package be detached even though other attached packages depend on it?

**Details**

This is most commonly used with a single number argument referring to a position on the search list, and can also be used with a unquoted or quoted name of an item on the search list such as `package:tools`.

If a package has a namespace, detaching it does not by default unload the namespace (and may not even with `unload = TRUE`), and detaching will not in general unload any dynamically loaded compiled code (DLLs); see `getLoadedDLLs` and `library.dynam.unload`. Further, registered S3 methods from the namespace will not be removed, and because S3 methods are not tagged to their source on registration, it is in general not possible to safely un-register the methods associated with a given package. If you use `library` on a package whose namespace is loaded, it attaches the exports of the already loaded namespace. So detaching and re-attaching a package may not refresh some or all components of the package, and is inadvisable. The most reliable way to completely detach a package is to restart R.

**Value**

The return value is invisible. It is `NULL` when a package is detached, otherwise the environment which was returned by `attach` when the object was attached (incorporating any changes since it was attached).
**Good practice**

`detach()` without an argument removes the first item on the search path after the workspace. It is all too easy to call it too many or too few times, or to not notice that the search path has changed since an `attach` call.

Use of `attach/detach` is best avoided in functions (see the help for `attach`) and in interactive use and scripts it is prudent to detach by name.

**Note**

You cannot detach either the workspace (position 1) nor the `base` package (the last item in the search list), and attempting to do so will throw an error.

Unloading some namespaces has undesirable side effects: e.g., unloading `grid` closes all graphics devices, and on some systems `tcltk` cannot be reloaded once it has been unloaded and may crash R if this is attempted.

**References**

**See Also**

`attach`, `library`, `search`, `objects`, `unloadNamespace`, `library.dynam.unload`.

**Examples**

```r
require(splines) # package
detach(package=splines)
## or also
library(splines)
pkg <- "package:splines"
detach(pkg, character.only = TRUE)

## careful: do not do this unless 'splines' is not already attached.
library(splines)
detach(2) # 'pos' used for 'name'

## an example of the name argument to attach
## and of detaching a database named by a character vector
attach_and_detach <- function(db, pos = 2)
{
  name <- deparse1(substitute(db))
  attach(db, pos = pos, name = name)
  print(search()[pos])
  detach(name, character.only = TRUE)
}
attach_and_detach(women, pos = 3)
```
**Description**

Extract or replace the diagonal of a matrix, or construct a diagonal matrix.

**Usage**

```r
diag(x = 1, nrow, ncol, names = TRUE)
diag(x) <- value
```

**Arguments**

- `x`: a matrix, vector or 1D array, or missing.
- `nrow, ncol`: optional dimensions for the result when `x` is not a matrix.
- `names`: (when `x` is a matrix) logical indicating if the resulting vector, the diagonal of `x`, should inherit `names` from `dimnames(x)` if available.
- `value`: either a single value or a vector of length equal to that of the current diagonal. Should be of a mode which can be coerced to that of `x`.

**Details**

diag has four distinct usages:

1. `x` is a matrix, when it extracts the diagonal.
2. `x` is missing and `nrow` is specified, it returns an identity matrix.
3. `x` is a scalar (length-one vector) and the only argument, it returns a square identity matrix of size given by the scalar.
4. `x` is a ‘numeric’ (complex, numeric, integer, logical, or raw) vector, either of length at least 2 or there were further arguments. This returns a matrix with the given diagonal and zero off-diagonal entries.

It is an error to specify `nrow` or `ncol` in the first case.

**Value**

If `x` is a matrix then `diag(x)` returns the diagonal of `x`. The resulting vector will have `names` if the matrix `x` has matching column and rownames.

The replacement form sets the diagonal of the matrix `x` to the given value(s).

In all other cases the value is a diagonal matrix with `nrow` rows and `ncol` columns (if `ncol` is not given the matrix is square). Here `nrow` is taken from the argument if specified, otherwise inferred from `x`: if that is a vector (or 1D array) of length two or more, then its length is the number of rows, but if it is of length one and neither `nrow` nor `ncol` is specified, `nrow = as.integer(x)`.

When a diagonal matrix is returned, the diagonal elements are one except in the fourth case, when `x` gives the diagonal elements: it will be recycled or truncated as needed, but fractional recycling and truncation will give a warning.
Note

Using `diag(x)` can have unexpected effects if `x` is a vector that could be of length one. Use `diag(x, nrow = length(x))` for consistent behaviour.

References

`upper.tri`, `lower.tri`, `matrix`.

Examples

dim(diag(3))
diag(10, 3, 4) # guess what?
all(diag(1:3) == (m <- matrix(0,3,3); diag(m) <- 1:3; m))

## other "numeric"-like diagonal matrices :
diag(c(1i,2i)) # complex
diag(TRUE, 3) # logical
diag(as.raw(1:3)) # raw

(D2 <- diag(2:1, 4)); typeof(D2) # "integer"

require(stats)
## diag(<var-cov-matrix>) = variances
diag(var(M <- cbind(X = 1:5, Y = rnorm(5))))
#-> vector with names "X" and "Y"
rownames(M) <- c(colnames(M), rep("", 3))
M; diag(M) # named as well
diag(M, names = FALSE) # w/o names

\[
\text{diff} \quad \text{Lagged Differences}
\]

Description

Returns suitably lagged and iterated differences.

Usage

diff(x, ...)

## Default S3 method:
diff(x, lag = 1, differences = 1, ...)

## S3 method for class 'POSIXt'
diff(x, lag = 1, differences = 1, ...)

## S3 method for class 'Date'
diff(x, lag = 1, differences = 1, ...)
Arguments

- `x`: a numeric vector or matrix containing the values to be differenced.
- `lag`: an integer indicating which lag to use.
- `differences`: an integer indicating the order of the difference.
- `...`: further arguments to be passed to or from methods.

Details

diff is a generic function with a default method and ones for classes "ts", "POSIXt" and "Date". NA’s propagate.

Value

If `x` is a vector of length `n` and `differences = 1`, then the computed result is equal to the successive differences \( x[(1+\text{lag}):n] - x[1:(n-\text{lag})] \).

If `differences` is larger than one this algorithm is applied recursively to `x`. Note that the returned value is a vector which is shorter than `x`.

If `x` is a matrix then the difference operations are carried out on each column separately.

Examples

diff(1:10, 2)
diff(1:10, 2, 2)
x <- cumsum(cumsum(1:10))
diff(x, lag = 2)
diff(x, differences = 2)
diff(.leap.seconds)

difftime

Time Intervals / Differences

Description

Time intervals creation, printing, and some arithmetic. The `print()` method calls these “time differences”.
```
Usage

diff(time1 - time2)

diff(time1, time2, tz,
    units = c("auto", "secs", "mins", "hours",
              "days", "weeks"))

as.diff(time, format = "%X", units = "auto", tz = "UTC")

## S3 method for class 'diff'
format(x, ...)

## S3 method for class 'diff'
units(x)

## S3 replacement method for class 'diff'
units(x) <- value

## S3 method for class 'diff'
as.double(x, units = "auto", ...)

## Group methods, notably for round(), signif(), floor(),
## ceiling(), trunc(), abs(); called directly, *not* as Math():
## S3 method for class 'diff'
Math(x, ...)
```

Arguments

time1, time2  date-time or date objects.
tz  an optional time zone specification to be used for the conversion, mainly for
POSIXlt objects.
units  character string. Units in which the results are desired. Can be abbreviated.
value  character string. Like units, except that abbreviations are not allowed.
tim  character string or numeric value specifying a time interval.
format  character specifying the format of tim: see strftime. The default is a locale-
specific time format.
x  an object inheriting from class "diff".
...  arguments to be passed to or from other methods.

Details

Function `diff` calculates a difference of two date/time objects and returns an object of class
"difftime" with an attribute indicating the units. The `Math` group method provides `round`, `signif`,
`floor`, `ceiling`, `trunc`, `abs`, and `sign` methods for objects of this class, and there are methods for
the group-generic (see `Ops`) logical and arithmetic operations.

If `units = "auto"`, a suitable set of units is chosen, the largest possible (excluding "weeks") in
which all the absolute differences are greater than one.

Subtraction of date-time objects gives an object of this class, by calling `diff` with `units =
"auto"`. Alternatively, `as.difftime()` works on character-coded or numeric time intervals; in the
latter case, units must be specified, and `format` has no effect.

Limited arithmetic is available on "difftime" objects: they can be added or subtracted, and
multiplied or divided by a numeric vector. In addition, adding or subtracting a numeric vector by a
"difftime" object implicitly converts the numeric vector to a "difftime" object with the same units as the "difftime" object. There are methods for \texttt{mean} and \texttt{sum} (via the \texttt{Summary} group generic), and \texttt{diff} via \texttt{diff.default} building on the "difftime" method for arithmetic, notably \texttt{-}.

The units of a "difftime" object can be extracted by the \texttt{units} function, which also has a replacement form. If the units are changed, the numerical value is scaled accordingly. The replacement version keeps attributes such as names and dimensions.

Note that \texttt{units = "days"} means a period of 24 hours, hence takes no account of Daylight Savings Time. Differences in objects of class "Date" are computed as if in the UTC time zone.

The \texttt{as.double} method returns the numeric value expressed in the specified units. Using \texttt{units = "auto"} means the units of the object.

The \texttt{format} method simply formats the numeric value and appends the units as a text string.

\textbf{Note}\n
Units such as "months" are not possible as they are not of constant length. To create intervals of months, quarters or years use \texttt{seq.Date} or \texttt{seq.POSIXt}.

\textbf{See Also}\n
\texttt{DateTimeClasses}.

\textbf{Examples}\n
\begin{verbatim}
(z <- Sys.time() - 3600)
Sys.time() - z # just over 3600 seconds.

## time interval between release days of R 1.2.2 and 1.2.3.

as.difftime(c("0:3:20", "11:23:15"))
as.difftime(c("3:20", "23:15", "2:"), format = "%H:%M") # 3rd gives NA
(z <- as.difftime(c(0,30,60), units = "mins"))
as.numeric(z, units = "secs")
as.numeric(z, units = "hours")
format(z)
\end{verbatim}

\textbf{dim} \hspace{1cm} Dimensions of an Object

\textbf{Description}\n
Retrieve or set the dimension of an object.

\textbf{Usage}\n
\begin{verbatim}
dim(x)
dim(x) <- value
\end{verbatim}
Arguments

- **x**: An R object, for example a matrix, array or data frame.
- **value**: For the default method, either NULL or a numeric vector, which is coerced to integer (by truncation).

Details

The functions `dim` and `dim<-` are internal generic primitive functions.

`dim` has a method for `data.frames`, which returns the lengths of the `row.names` attribute of `x` and of `x` (as the numbers of rows and columns respectively).

Value

For an array (and hence in particular, for a matrix) `dim` retrieves the `dim` attribute of the object. It is NULL or a vector of mode integer.

The replacement method changes the "dim" attribute (provided the new value is compatible) and removes any "dimnames" and "names" attributes.

References

See Also

`ncol`, `nrow` and `dimnames`.

Examples

```r
x <- 1:12 ; dim(x) <- c(3,4)
x
# simple versions of nrow and ncol could be defined as follows
nrow0 <- function(x) dim(x)[1]
ncol0 <- function(x) dim(x)[2]
```

---

**Dimnames of an Object**

Description

Retrieve or set the dimnames of an object.

Usage

```r
dimnames(x)
dimnames(x) <- value
```

provideDimnames(x, sep = "", base = list(LETTERS), unique = TRUE)
Arguments

x  an R object, for example a matrix, array or data frame.
value a possible value for dimnames(x): see the 'Value' section.
sep   a character string, used to separate base symbols and digits in the constructed
dimnames.
base a non-empty list of character vectors. The list components are used in turn
 (and recycled when needed) to construct replacements for empty dimnames
 components. See also the examples.
unique logical indicating that the dimnames constructed are unique within each dimen-
sion in the sense of make.unique.

Details

The functions dimnames and dimnames<- are generic.
For an array (and hence in particular, for a matrix), they retrieve or set the
dimnames attribute (see attributes) of the object. A list value can have names, and these will be used to label the dimensions
of the array where appropriate.
The replacement method for arrays/matrices coerces vector and factor elements of value to charac-
ter, but does not dispatch methods for as.character. It coerces zero-length elements to NULL, and
a zero-length list to NULL. If value is a list shorter than the number of dimensions, it is extended
with NULLs to the needed length.
Both have methods for data frames. The dimnames of a data frame are its row.names and its names.
For the replacement method each component of value will be coerced by as.character.
For a 1D matrix the names are the same thing as the (only) component of the dimnames.
Both are primitive functions.
provideDimnames(x) provides dimnames where “missing”, such that its result has character dim-
names for each component. If unique is true as by default, they are unique within each component
via make.unique(*,sep=sep).

Value

The dimnames of a matrix or array can be NULL (which is not stored) or a list of the same length
as dim(x). If a list, its components are either NULL or a character vector with positive length of the
appropriate dimension of x. The list can have names. It is possible that all components are NULL:
such dimnames may get converted to NULL.
For the "data.frame" method both dimnames are character vectors, and the rownames must con-
tain no duplicates nor missing values.
provideDimnames(x) returns x, with “NULL - free” dimnames, i.e. each component a character
vector of correct length.

Note

Setting components of the dimnames, e.g., dimnames(A)[[1]] <- value is a common paradigm,
but note that it will not work if the value assigned is NULL. Use rownames instead, or (as it does)
manipulate the whole dimnames list.

References

Brooks/Cole.

rownames, colnames; array, matrix, data.frame.

Examples

## simple versions of rownames and colnames
## could be defined as follows
rownames0 <- function(x) dimnames(x)[[1]]
colnames0 <- function(x) dimnames(x)[[2]]

(dn <- dimnames(A <- provideDimnames(N <- array(1:24, dim = 2:4))))
A0 <- A; dimnames(A)[2:3] <- list(NULL)
stopifnot(identical(A0, provideDimnames(A)))
strd <- function(x) utils::str(dimnames(x))
strd(provideDimnames(A, base= list(letters[-(1:9)], tail(LETTERS))))
strd(provideDimnames(N, base= list(letters[-(1:9)], tail(LETTERS)))) # recycling
strd(provideDimnames(A, base= list(c("AA","BB")))) # recycling on both levels
## set "empty dimnames":
provideDimnames(rbind(1, 2:3), base = list(""), unique=FALSE)

---

**do.call**

Execute a Function Call

**Description**

`do.call` constructs and executes a function call from a name or a function and a list of arguments to be passed to it.

**Usage**

```r
do.call(what, args, quote = FALSE, envir = parent.frame())
```

**Arguments**

- **what**: either a function or a non-empty character string naming the function to be called.
- **args**: a list of arguments to the function call. The `names` attribute of `args` gives the argument names.
- **quote**: a logical value indicating whether to quote the arguments.
- **envir**: an environment within which to evaluate the call. This will be most useful if what is a character string and the arguments are symbols or quoted expressions.

**Details**

If `quote` is `FALSE`, the default, then the arguments are evaluated (in the calling environment, not in `envir`). If `quote` is `TRUE` then each argument is quoted (see `quote`) so that the effect of argument evaluation is to remove the quotes – leaving the original arguments unevaluated when the call is constructed.

The behavior of some functions, such as `substitute`, will not be the same for functions evaluated using `do.call` as if they were evaluated from the interpreter. The precise semantics are currently undefined and subject to change.
Value

The result of the (evaluated) function call.

Warning

This should not be used to attempt to evade restrictions on the use of .Internal and other non-API calls.

References

`call` which creates an unevaluated call.

Examples

do.call("complex", list(imag = 1:3))

## if we already have a list (e.g., a data frame)
## we need c() to add further arguments
tmp <- expand.grid(letters[1:2], 1:3, c("+", "-"))
do.call("paste", c(tmp, sep = ""))

do.call(paste, list(as.name("A"), as.name("B")), quote = TRUE)

## examples of where objects will be found.
A <- 2
f <- function(x) print(x^2)
env <- new.env()
assign("A", 10, envir = env)
assign("f", f, envir = env)
f <- function(x) print(x)
f(A) # 2
do.call("f", list(A)) # 2
do.call("f", list(A), envir = env) # 4
do.call( f, list(A), envir = env) # 2
do.call("f", list(quote(A)), envir = env) # 100
do.call( f, list(quote(A)), envir = env) # 10
do.call("f", list(as.name("A")), envir = env) # 100

eval(call("f", A)) # 2
eval(call("f", quote(A))) # 2
eval(call("f", A), envir = env) # 4
eval(call("f", quote(A)), envir = env) # 100
Identity Function to Suppress Checking

dontCheck

Description

The `dontCheck` function is the same as `identity`, but is interpreted by `R CMD check` code analysis as a directive to suppress checking of `x`. Currently this is only used by `checkFF(registration = TRUE)` when checking the `.NAME` argument of foreign function calls.

Usage

dontCheck(x)

Arguments

- `x` an R object.

See Also

`suppressForeignCheck` which explains why that and `dontCheck` are undesirable and should be avoided if at all possible.

dots ..........1, etc used in Functions

Description

... and ..1, ..2 etc are used to refer to arguments passed down from a calling function. These (and the following) can only be used inside a function which has ... among its formal arguments.

...elt(n) is a functional way to get ..<n> and basically the same as `eval(paste0("..",n))`, just more elegant and efficient. Note that `switch(n,...)` is very close, differing by returning `NULL` invisibly instead of an error when `n` is zero or too large.

...length() returns the number of expressions in ..., and ...names() the `names`. These are the same as `length(list(...))` or `names(list(...))` but without evaluating the expressions in ... (which happens with `list(...)`).

Evaluating elements of ... with ..1, ..2, ...elt(n), etc. propagates `visibility`. This is consistent with the evaluation of named arguments which also propagates visibility.

Usage

...length()
...names()
...elt(n)

Arguments

- `n` a positive integer, not larger than the number of expressions in ...., which is the same as ...length() which is the same as `length(list(...))`, but the latter evaluates all expressions in ....
See Also

... and .1...2 are reserved words in R, see Reserved.
For more, see the 'Introduction to R' manual for usage of these syntactic elements, and dotsMethods
for their use in formal (S4) methods.

Examples

tst <- function(n, ...) ...elt(n)
tst(1, pi=pi*0:1, 2:4) ## [1] 0.000000 3.141593
tst(2, pi=pi*0:1, 2:4) ## [1] 2 3 4
try(tst(1)) # -> Error about '...' not containing an element.

tst.dl <- function(x, ...) ...length()
tst.dns <- function(x, ...) ...names()
tst.dl(1:10) # 0 (because the first argument is 'x')
tst.dl(4, 5) # 1
tst.dl(4, 5, 6) # 2 namely '5, 6'
tst.dl(4, 5, 6, 7, sin(1:10), "foo"/"bar") # 5. Note: no evaluation!
tst.dns(4, foo=5, 6, bar=7, sini = sin(1:10), "foo"/"bar")
# "foo" NA "bar" "sini" NA

---

double

Double-Precision Vectors

Description

Create, coerce to or test for a double-precision vector.

Usage

double(length = 0)
as.double(x, ...)
is.double(x)

single(length = 0)
as.single(x, ...)

Arguments

length A non-negative integer specifying the desired length. Double values will be coerced to integer: supplying an argument of length other than one is an error.
x object to be coerced or tested.
... further arguments passed to or from other methods.

Details

double creates a double-precision vector of the specified length. The elements of the vector are all equal to 0. It is identical to numeric.
as.double is a generic function. It is identical to as.numeric. Methods should return an object of base type "double".
is.double is a test of double type.
**double**

R has no single precision data type. All real numbers are stored in double precision format. The functions as.single and single are identical to as.double and double except they set the attribute Csingle that is used in the .C and .Fortran interface, and they are intended only to be used in that context.

**Value**

double creates a double-precision vector of the specified length. The elements of the vector are all equal to 0.

as.double attempts to coerce its argument to be of double type: like as.vector it strips attributes including names. (To ensure that an object is of double type without stripping attributes, use storage.mode.) Character strings containing optional whitespace followed by either a decimal representation or a hexadecimal representation (starting with 0x or 0X) can be converted, as can special values such as "NA", "NaN", "Inf" and "infinity", irrespective of case.

as.double for factors yields the codes underlying the factor levels, not the numeric representation of the labels, see also factor.

is.double returns TRUE or FALSE depending on whether its argument is of double type or not.

**Double-precision values**

All R platforms are required to work with values conforming to the IEC 60559 (also known as IEEE 754) standard. This basically works with a precision of 53 bits, and represents to that precision a range of absolute values from about $2 \times 10^{-308}$ to $2 \times 10^{308}$. It also has special values NaN (many of them), plus and minus infinity and plus and minus zero (although R acts as if these are the same). There are also denormal(ized) (or subnormal) numbers with absolute values above or below the range given above but represented to less precision.

See .Machine for precise information on these limits. Note that ultimately how double precision numbers are handled is down to the CPU/FPU and compiler.

In IEEE 754-2008/IEC60559:2011 this is called ‘binary64’ format.

**Note on names**

It is a historical anomaly that R has two names for its floating-point vectors, double and numeric (and formerly had real).

double is the name of the type. numeric is the name of the mode and also of the implicit class. As an S4 formal class, use "numeric".

The potential confusion is that R has used mode "numeric" to mean ‘double or integer’, which conflicts with the S4 usage. Thus is.numeric tests the mode, not the class, but as.numeric (which is identical to as.double) coerces to the class.

**References**

**dput**

Write an Object to a File or Recreate it

**Description**

Writes an ASCII text representation of an R object to a file, the R console, or a connection, or uses one to recreate the object.

**Usage**

```r
dput(x, file = "", control = c("keepNA", "keepInteger", "niceNames", "showAttributes"))

dget(file, keep.source = FALSE)
```

**Arguments**

- `x`: an object.
- `file`: either a character string naming a file or a connection. "" indicates output to the console.
- `control`: character vector indicating deparsing options. See `.deparseOpts` for their description.
- `keep.source`: logical: should the source formatting be retained when parsing functions, if possible?

**Details**

dput opens file and deparses the object x into that file. The object name is not written (unlike `dump`). If x is a function the associated environment is stripped. Hence scoping information can be lost.

Deparsing an object is difficult, and not always possible. With the default control, `dput()` attempts to deparse in a way that is readable, but for more complex or unusual objects (see `dump`), not likely to be parsed as identical to the original. Use `control = "all"` for the most complete deparsing; use `control = NULL` for the simplest deparsing, not even including attributes.

dput will warn if fewer characters were written to a file than expected, which may indicate a full or corrupt file system.

To display saved source rather than deparsing the internal representation include "useSource" in control. R currently saves source only for function definitions. If you do not care about source representation (e.g., for a data object), for speed set `options(keep.source = FALSE)` when calling source.

**See Also**

`integer`, `numeric`, `storage.mode`.

**Examples**

```r
is.double(1)
all(double(3) == 0)
```
Value

For dput, the first argument invisibly.
For dget, the object created.

Note

This is not a good way to transfer objects between \texttt{R} sessions. \texttt{dump} is better, but the functions \texttt{save} and \texttt{saveRDS} are designed to be used for transporting \texttt{R} data, and will work with \texttt{R} objects that \texttt{dput} does not handle correctly as well as being much faster.

To avoid the risk of a source attribute out of sync with the actual function definition, the source attribute of a function will never be written as an attribute.

References

See Also

deparse, dump, write.

Examples

```r
fil <- tempfile()
## Write an ASCII version of the 'base' function mean() to our temp file, ..
dput(base::mean, fil)
## ... read it back into 'bar' and confirm it is the same
bar <- dget(fil)
stopifnot(all.equal(bar, base::mean, check.environments = FALSE))

## Create a function with comments
baz <- function(x) {
  # Subtract from one
  1-x
}
## and display it
dput(baz)
## and now display the saved source
dput(baz, control = "useSource")

## Numeric values:
xx <- pi^c(1:3)
dput(xx)
dput(xx, control = "digits17")
dput(xx, control = "hexNumeric")
dput(xx, fil); dget(fil) - xx # slight rounding on all platforms
dput(xx, fil, control = "digits17")
dget(fil) - xx # slight rounding on some platforms
dput(xx, fil, control = "hexNumeric"); dget(fil) - xx
unlink(fil)

xn <- setNames(xx, paste0("pi",^c(1:3)))
dput(xn) # nicer, now "niceNames" being part of default 'control'
dput(xn, control = "S_compat") # no names
## explicitly asking for output as in R < 3.5.0:
```
### drop

**Drop Redundant Extent Information**

**Description**

Delete the dimensions of an array which have only one level.

**Usage**

```
drop(x)
```

**Arguments**

- `x`: an array (including a matrix).

**Value**

If `x` is an object with a `dim` attribute (e.g., a matrix or `array`), then `drop` returns an object like `x`, but with any extents of length one removed. Any accompanying `dimnames` attribute is adjusted and returned with `x`: if the result is a vector the names are taken from the `dimnames` (if any). If the result is a length-one vector, the names are taken from the first dimension with a `dimname`.

Array subsetting ([]) performs this reduction unless used with `drop = FALSE`, but sometimes it is useful to invoke `drop` directly.

**See Also**

- `drop1` which is used for dropping terms in models.

**Examples**

```
dim(drop(array(1:12, dim = c(1,3,1,1,2,1,2)))) # = 3 2 2
drop(1:3 %% 2:4) # scalar product
```

### droplevels

**Drop Unused Levels from Factors**

**Description**

The function `droplevels` is used to drop unused levels from a `factor` or, more commonly, from factors in a data frame.

**Usage**

```
## S3 method for class 'factor'
droplevels(x, exclude = if(anyNA(levels(x))) NULL else NA, ...)
## S3 method for class 'data.frame'
droplevels(x, except, exclude, ...)
```
Arguments

x  an object from which to drop unused factor levels.
exclude  passed to factor(): factor levels which should be excluded from the result even if present. Note that this was implicitly NA in R <= 3.3.1 which did drop NA levels even when present in x, contrary to the documentation. The current default is compatible with x[,drop=TRUE].
...  further arguments passed to methods
except  indices of columns from which not to drop levels

Details

The method for class "factor" is currently equivalent to factor(x,exclude=exclude). For the data frame method, you should rarely specify exclude “globally” for all factor columns; rather the default uses the same factor-specific exclude as the factor method itself. The except argument follow the usual indexing rules.

Value
droplevels returns an object of the same class as x

Note

This function was introduced in R 2.12.0. It is primarily intended for cases where one or more factors in a data frame contains only elements from a reduced level set after subsetting. (Notice that subsetting does not in general drop unused levels). By default, levels are dropped from all factors in a data frame, but the except argument allows you to specify columns for which this is not wanted.

See Also

subset for subsetting data frames. factor for definition of factors. drop for dropping array dimensions. drop1 for dropping terms from a model. [.factor for subsetting of factors.

Examples

aq <- transform(airquality, Month = factor(Month, labels = month.abb[5:9]))
aq <- subset(aq, Month != "Jul")
table(aq $Month)
table(droplevels(aq)$Month)

dump

Text Representations of R Objects

Description

This function takes a vector of names of R objects and produces text representations of the objects on a file or connection. A dump file can usually be sourced into another R session.

Usage

dump(list, file = "dumpdata.R", append = FALSE, control = "all", envir = parent.frame(), evaluate = TRUE)
dump

Arguments

- **list**: character vector. The names of one or more R objects to be dumped.
- **file**: either a character string naming a file or a connection. """" indicates output to the console.
- **append**: if TRUE and file is a character string, output will be appended to file; otherwise, it will overwrite the contents of file.
- **control**: character vector indicating deparsing options. See .deparseOpts for their description.
- **envir**: the environment to search for objects.
- **evaluate**: logical. Should promises be evaluated?

Details

If some of the objects named do not exist (in scope), they are omitted, with a warning. If file is a file and no objects exist then no file is created.

`source`ing may not produce an identical copy of dumped objects. A warning is issued if it is likely that problems will arise, for example when dumping exotic or complex objects (see the Note). `dump` will also warn if fewer characters were written to a file than expected, which may indicate a full or corrupt file system.

A dump file can be `sourced` into another R (or perhaps S) session, but the functions `save` and `saveRDS` are designed to be used for transporting R data, and will work with R objects that `dump` does not handle. For maximal reproducibility use `control = c("all","hexNumeric")`.

To produce a more readable representation of an object, use `control = NULL`. This will skip attributes, and will make other simplifications that make `source` less likely to produce an identical copy. See `deparse` for details.

To deparse the internal representation of a function rather than displaying the saved source, use `control = c("keepInteger","warnIncomplete","keepNA")`. This will lose all formatting and comments, but may be useful in those cases where the saved source is no longer correct.

Promises will normally only be encountered by users as a result of lazy-loading (when the default `evaluate = TRUE` is essential) and after the use of `delayedAssign`, when `evaluate = FALSE` might be intended.

Value

An invisible character vector containing the names of the objects which were dumped.

Note

As `dump` is defined in the base namespace, the **base** package will be searched before the global environment unless `dump` is called from the top level prompt or the `envir` argument is given explicitly.

To avoid the risk of a source attribute becoming out of sync with the actual function definition, the source attribute of a function will never be dumped as an attribute.

Currently environments, external pointers, weak references and objects of type S4 are not deparsed in a way that can be `sourced`. In addition, **language objects** are deparsed in a simple way whatever the value of `control`, and this includes not dumping their attributes (which will result in a warning).

References

duplicated

See Also

.deparseOpts for available control settings; dput(), dget() and deparse() for related functions using identical internal deparsing functionality.
write, write.table, etc for “dumping” data to (text) files.
save and saveRDS for a more reliable way to save R objects.

Examples

x <- 1:10
fil <- tempfile(fileext=".Rdump")
dump(ls(pattern = '^xyz'), fil)
print(.Last.value)
unlink(fil)

duplicated Determine Duplicate Elements

Description
duplicated() determines which elements of a vector or data frame are duplicates of elements with smaller subscripts, and returns a logical vector indicating which elements (rows) are duplicates.
anyDuplicated(.) is a “generalized” more efficient shortcut for any(duplicated(.)).

Usage
duplicated(x, incomparables = FALSE, ...)

## Default S3 method:
duplicated(x, incomparables = FALSE,
    fromLast = FALSE, nmax = NA, ...)

## S3 method for class array
duplicated(x, incomparables = FALSE, MARGIN = 1,
    fromLast = FALSE, ...)

anyDuplicated(x, incomparables = FALSE, ...)

## Default S3 method:
anyDuplicated(x, incomparables = FALSE,
    fromLast = FALSE, ...)

## S3 method for class array
anyDuplicated(x, incomparables = FALSE,
    MARGIN = 1, fromLast = FALSE, ...)

Arguments

x a vector or a data frame or an array or NULL.
incomparables a vector of values that cannot be compared. FALSE is a special value, meaning that all values can be compared, and may be the only value accepted for methods other than the default. It will be coerced internally to the same type as x.
fromLast  logical indicating if duplication should be considered from the reverse side, i.e.,
the last (or rightmost) of identical elements would correspond to duplicated = FALSE.
nmax  the maximum number of unique items expected (greater than one).
...  arguments for particular methods.
MARGIN  the array margin to be held fixed: see apply, and note that MARGIN = 0 may be
useful.

Details

These are generic functions with methods for vectors (including lists), data frames and arrays (in-
cluding matrices).
For the default methods, and whenever there are equivalent method definitions for
duplicated and anyDuplicated, anyDuplicated(x,...) is a “generalized” shortcut for
any(duplicated(x,...)), in the sense that it returns the index i of the first duplicated entry x[i]
if there is one, and 0 otherwise. Their behaviours may be different when at least one of duplicated
and anyDuplicated has a relevant method.
duplicated(x,fromLast = TRUE) is equivalent to but faster than rev(duplicated(rev(x))).
The array method calculates for each element of the sub-array specified by MARGIN if the remaining
dimensions are identical to those for an earlier (or later, when fromLast = TRUE) element (in row-
major order). This would most commonly be used to find duplicated rows (the default) or columns
(with MARGIN = 2). Note that MARGIN = 0 returns an array of the same dimensionality attributes as x.
Missing values ("NA") are regarded as equal, numeric and complex ones differing from NaN; char-
acter strings will be compared in a “common encoding”; for details, see match (and unique) which
use the same concept.
Values in incomparables will never be marked as duplicated. This is intended to be used for a
fairly small set of values and will not be efficient for a very large set.
Except for factors, logical and raw vectors the default nmax = NA is equivalent to nmax = length(x).
Since a hash table of size 8*nmax bytes is allocated, setting nmax suitably can save large amounts
of memory. For factors it is automatically set to the smaller of length(x) and the number of levels
plus one (for NA). If nmax is set too small there is liable to be an error: nmax = 1 is silently ignored.
Long vectors are supported for the default method of duplicated, but may only be usable if nmax
is supplied.

Value
duplicated(): For a vector input, a logical vector of the same length as x. For a data frame, a
logical vector with one element for each row. For a matrix or array, and when MARGIN = 0, a logical
array with the same dimensions and dimnames.
anyDuplicated(): an integer or real vector of length one with value the 1-based index of the first
duplicate if any, otherwise 0.

Warning

Using this for lists is potentially slow, especially if the elements are not atomic vectors (see vector)
or differ only in their attributes. In the worst case it is O(n^2).

unique.

Examples

```r
x <- c(9:20, 1:5, 3:7, 0:8)
## extract unique elements
(xu <- x[!duplicated(x)])
## similar, same elements but different order:
(xu2 <- x[!duplicated(x, fromLast = TRUE)])

## xu == unique(x) but unique(x) is more efficient
stopifnot(identical(xu, unique(x)),
          identical(xu2, unique(x, fromLast = TRUE)))

duplicated(iris)[140:143]
duplicated(iris3, MARGIN = c(1, 3))
anyDuplicated(iris)  ## 143

anyDuplicated(x)
anyDuplicated(x, fromLast = TRUE)
```

dyn.load

Foreign Function Interface

Description

Load or unload DLLs (also known as shared objects), and test whether a C function or Fortran subroutine is available.

Usage

dyn.load(x, local = TRUE, now = TRUE, ...)
dyn.unload(x)

is.loaded(symbol, PACKAGE = "", type = "")

Arguments

- `x` a character string giving the pathname to a DLL, also known as a dynamic shared object. (See ‘Details’ for what these terms mean.)

- `local` a logical value controlling whether the symbols in the DLL are stored in their own local table and not shared across DLLs, or added to the global symbol table. Whether this has any effect is system-dependent.

- `now` a logical controlling whether all symbols are resolved (and relocated) immediately the library is loaded or deferred until they are used. This control is useful for developers testing whether a library is complete and has all the necessary symbols, and for users to ignore missing symbols. Whether this has any effect is system-dependent.

- `...` other arguments for future expansion.
symbol

A character string giving a symbol name.

PACKAGE

If supplied, confine the search for the name to the DLL given by this argument (plus the conventional extension, `.so`, `.s1`, `.dll`, `...`). This is intended to add safety for packages, which can ensure by using this argument that no other package can override their external symbols. This is used in the same way as in `.C`, `.Call`, `.Fortran` and `.External` functions.

type

The type of symbol to look for: can be any ("", the default), "Fortran", "Call" or "External".

Details

The objects `dyn.load` loads are called ‘dynamically loadable libraries’ (abbreviated to ‘DLL’) on all platforms except macOS, which uses the term for a different sort of object. On Unix-alikes they are also called ‘dynamic shared objects’ (‘DSO’), or ‘shared objects’ for short. (The POSIX standards use ‘executable object file’, but no one else does.)

See ‘See Also’ and the ‘Writing R Extensions’ and ‘R Installation and Administration’ manuals for how to create and install a suitable DLL.

Unfortunately a very few platforms (e.g., Compaq Tru64) do not handle the `PACKAGE` argument correctly, and may incorrectly find symbols linked into `R`. The additional arguments to `dyn.load` mirror the different aspects of the mode argument to the `dlopen()` routine on POSIX systems. They are available so that users can exercise greater control over the loading process for an individual library. In general, the default values are appropriate and you should override them only if there is good reason and you understand the implications.

The `local` argument allows one to control whether the symbols in the DLL being attached are visible to other DLLs. While maintaining the symbols in their own namespace is good practice, the ability to share symbols across related ‘chapters’ is useful in many cases. Additionally, on certain platforms and versions of an operating system, certain libraries must have their symbols loaded globally to successfully resolve all symbols.

One should be careful of the potential side-effect of using lazy loading via the `now` argument as `FALSE`. If a routine is called that has a missing symbol, the process will terminate immediately. The intended use is for library developers to call with value `TRUE` to check that all symbols are actually resolved and for regular users to call with `FALSE` so that missing symbols can be ignored and the available ones can be called.

The initial motivation for adding these was to avoid such termination in the `_init()` routines of the Java virtual machine library. However, symbols loaded locally may not be (read probably) available to other DLLs. Those added to the global table are available to all other elements of the application and so can be shared across two different DLLs.

Some (very old) systems do not provide (explicit) support for local/global and lazy/eager symbol resolution. This can be the source of subtle bugs. One can arrange to have warning messages emitted when unsupported options are used. This is done by setting either of the options `verbose` or `warn` to be non-zero via the `options` function.

There is a short discussion of these additional arguments with some example code available at [http://www.stat.ucdavis.edu/~duncan/R/dynload/](http://www.stat.ucdavis.edu/~duncan/R/dynload/).

Value

The function `dyn.load` is used for its side effect which links the specified DLL to the executing `R` image. Calls to `.C`, `.Call`, `.Fortran` and `.External` can then be used to execute compiled C functions or Fortran subroutines contained in the library. The return value of `dyn.load` is an object of class `DLLInfo`. See `getLoadedDLLs` for information about this class.
The function `dyn.unload` unlinks the DLL. Note that unloading a DLL and then re-loading a DLL of the same name may or may not work: on Solaris it uses the first version loaded. Note also that some DLLs cannot be safely unloaded at all: unloading a DLL which implements C finalizers but does not unregister them on unload causes R to crash.

`is.loaded` checks if the symbol name is loaded and searchable and hence available for use as a character string value for argument `.NAME` in `.C` or `.Fortran` or `.Call` or `.External`. It will succeed if any one of the four calling functions would succeed in using the entry point unless type is specified. (See `.Fortran` for how Fortran symbols are mapped.) Note that symbols in base packages are not searchable, and other packages can be so marked.

**Warning**

Do not use `dyn.unload` on a DLL loaded by `library.dynam`: use `library.dynam.unload`. This is needed for system housekeeping.

**Note**

`is.loaded` requires the name you would give to `.C` etc and **not** (as in S) that remapped by the `defunct` functions `symbol.C` or `symbol.Fortran`.

By default, the maximum number of DLLs that can be loaded is now 614 when the OS limit on the number of open files allows or can be increased, but less otherwise (but it will be at least 100). A specific maximum can be requested via the environment variable `R_MAX_NUM_DLLS`, which has to be set (to a value between 100 and 1000 inclusive) before starting an R session. If the OS limit on the number of open files does not allow using this maximum and cannot be increased, R will fail to start with an error. The maximum is not allowed to be greater than 60% of the OS limit on the number of open files (essentially unlimited on Windows, on Unix typically 1024, but 256 on macOS). The limit can sometimes (including on macOS) be modified using command `ulimit -n` (sh, bash) or `limit descriptors` (csh) in the shell used to launch R. Increasing `R_MAX_NUM_DLLS` comes with some memory overhead.

If the OS limit on the number of open files cannot be determined, the DLL limit is 100 and cannot be changed via `R_MAX_NUM_DLLS`.

The creation of DLLs and the runtime linking of them into executing programs is very platform dependent. In recent years there has been some simplification in the process because the C subroutine call `dlopen` has become the POSIX standard for doing this. Under Unix-alikes `dyn.load` uses the `dlopen` mechanism and should work on all platforms which support it. On Windows it uses the standard mechanism (LoadLibrary) for loading DLLs.

The original code for loading DLLs in Unix-alikes was provided by Heiner Schwarte.

eapply

eapply

Apply a Function Over Values in an Environment

Description

eapply applies FUN to the named values from an environment and returns the results as a list. The user can request that all named objects are used (normally names that begin with a dot are not). The output is not sorted and no enclosing environments are searched.

Usage

eapply(env, FUN, ..., all.names = FALSE, USE.NAMES = TRUE)

Arguments

ev
environment to be used.
FUN
the function to be applied, found via match.fun. In the case of functions like +, %*%, etc., the function name must be backquoted or quoted.
...
optional arguments to FUN.
all.names
a logical indicating whether to apply the function to all values.
USE.NAMES
logical indicating whether the resulting list should have names.

Value

A named (unless USE.NAMES = FALSE) list. Note that the order of the components is arbitrary for hashed environments.

See Also

environment, lapply.

Examples

require(stats)

env <- new.env(hash = FALSE) # so the order is fixed
e$v$a <- 1:10
e$v$beta <- exp(-3:3)
e$v$logic <- c(TRUE, FALSE, FALSE, TRUE)
# what have we there?
utils::ls.str(env)

# compute the mean for each list element
eapply(env, mean)
unlist(eapply(env, mean, USE.NAMES = FALSE))
# median and quartiles for each element (making use of "..." passing):
eapply(env, quantile, probs = 1:3/4)
eapply(env, quantile)

---

eigen

**Spectral Decomposition of a Matrix**

**Description**
Computes eigenvalues and eigenvectors of numeric (double, integer, logical) or complex matrices.

**Usage**
eigen(x, symmetric, only.values = FALSE, EISPACK = FALSE)

**Arguments**
- **x**: a numeric or complex matrix whose spectral decomposition is to be computed. Logical matrices are coerced to numeric.
- **symmetric**: if TRUE, the matrix is assumed to be symmetric (or Hermitian if complex) and only its lower triangle (diagonal included) is used. If symmetric is not specified, `isSymmetric(x)` is used.
- **only.values**: if TRUE, only the eigenvalues are computed and returned, otherwise both eigenvalues and eigenvectors are returned.
- **EISPACK**: logical. Defunct and ignored.

**Details**
- If symmetric is unspecified, `isSymmetric(x)` determines if the matrix is symmetric up to plausible numerical inaccuracies. It is surer and typically much faster to set the value yourself.
- Computing the eigenvectors is the slow part for large matrices.
- Computing the eigendecomposition of a matrix is subject to errors on a real-world computer: the definitive analysis is Wilkinson (1965). All you can hope for is a solution to a problem suitably close to x. So even though a real asymmetric x may have an algebraic solution with repeated real eigenvalues, the computed solution may be of a similar matrix with complex conjugate pairs of eigenvalues.
- Unsuccessful results from the underlying LAPACK code will result in an error giving a positive error code (most often 1): these can only be interpreted by detailed study of the FORTRAN code.

**Value**
The spectral decomposition of x is returned as a list with components

- **values**: a vector containing the p eigenvalues of x, sorted in decreasing order, according to `Mod(values)` in the asymmetric case when they might be complex (even for real matrices). For real asymmetric matrices the vector will be complex only if complex conjugate pairs of eigenvalues are detected.
either a \( p \times p \) matrix whose columns contain the eigenvectors of \( x \), or NULL if only.values is TRUE. The vectors are normalized to unit length. 

Recall that the eigenvectors are only defined up to a constant: even when the length is specified they are still only defined up to a scalar of modulus one (the sign for real matrices).

When only.values is not true, as by default, the result is of S3 class "eigen".

If \( r <- \text{eigen}(A) \), and \( V <- r\$vectors \); \( \lambda <- r\$values \), then

\[
A = V \Lambda V^{-1}
\]

(up to numerical fuzz), where \( \Lambda = \text{diag}(\lambda) \).

Source

\text{eigen} uses the LAPACK routines \texttt{DSYEVR}, \texttt{DGEEV}, \texttt{ZHEEV} and \texttt{ZGEEV}.

LAPACK is from \texttt{https://www.netlib.org/lapack/} and its guide is listed in the references.

References

Available on-line at \texttt{https://www.netlib.org/lapack/lug/lapack_lug.html}.

See Also

\texttt{svd}, a generalization of \texttt{eigen}; \texttt{qr}, and \texttt{chol} for related decompositions.

To compute the determinant of a matrix, the \texttt{qr} decomposition is much more efficient: \texttt{det}.

Examples

\begin{verbatim}
eigen(cbind(c(1,-1), c(-1,1)))
eigen(cbind(c(1,-1), c(-1,1)), symmetric = FALSE) # same (different algorithm).
eigen(cbind(1, c(1,-1)), only.values = TRUE)
eigen(cbind(-1, 2:1)) # complex values
eigen(print(cbind(c(0, 1i), c(-1i, 0)))) # Hermite ==> real Eigenvalues
# 3 x 3:
eigen(cbind( 1, 3:1, 1:3))
eigen(cbind(-1, c(1:2,0), 0:2)) # complex values
\end{verbatim}
**encodeString**

**Encode Character Vector as for Printing**

**Description**

`encodeString` escapes the strings in a character vector in the same way `print.default` does, and optionally fits the encoded strings within a field width.

**Usage**

```r
encodeString(x, width = 0, quote = "", na.encode = TRUE, justify = c("left", "right", "centre", "none"))
```

**Arguments**

- **x**: A character vector, or an object that can be coerced to one by `as.character`.
- **width**: integer: the minimum field width. If NULL or NA, this is taken to be the largest field width needed for any element of `x`.
- **quote**: character: quoting character, if any.
- **na.encode**: logical: should NA strings be encoded?
- **justify**: character: partial matches are allowed. If padding to the minimum field width is needed, how should spaces be inserted? `justify == "none"` is equivalent to `width = 0`, for consistency with `format.default`.

**Details**

This escapes backslash and the control characters `\a` (bell), `\b` (backspace), `\f` (formfeed), `\n` (line feed), `\r` (carriage return), `\t` (tab) and `\v` (vertical tab) as well as any non-printable characters in a single-byte locale, which are printed in octal notation (`\xyz` with leading zeroes).

Which characters are non-printable depends on the current locale. Windows' reporting of printable characters is unreliable, so there all other control characters are regarded as non-printable, and all characters with codes 32–255 as printable in a single-byte locale. See `print.default` for how non-printable characters are handled in multi-byte locales.

If `quote` is a single or double quote any embedded quote of the same type is escaped. Note that justification is of the quoted string, hence spaces are added outside the quotes.

**Value**

A character vector of the same length as `x`, with the same attributes (including names and dimensions) but with no class set.

Marked UTF-8 encodings are preserved.

**Note**

The default for `width` is different from `format.default`, which does similar things for character vectors but without encoding using escapes.

**See Also**

`print.default`
Encoding

Examples

```r
x <- "ab\bc\ndef"
print(x)
cat(x) # interprets escapes
cat(encodeString(x), "\n", sep = "") # similar to print()

factor(x) # makes use of this to print the levels

x <- c("a", "ab", "abcde")
encodeString(x) # width = 0: use as little as possible
encodeString(x, 2) # use two or more (left justified)
encodeString(x, width = NA) # left justification
encodeString(x, width = NA, justify = "c")
encodeString(x, width = NA, justify = "r")
encodeString(x, width = NA, quote = "'/quotesingle.Var", justify = "r")
```

Description

Read or set the declared encodings for a character vector.

Usage

```r
Encoding(x)
Encoding(x) <- value
enc2native(x)
enc2utf8(x)
```

Arguments

- `x`: A character vector.
- `value`: A character vector of positive length.

Details

Character strings in R can be declared to be encoded in "latin1" or "UTF-8" or as "bytes". These declarations can be read by `Encoding`, which will return a character vector of values "latin1", "UTF-8" "bytes" or "unknown", or set, when `value` is recycled as needed and other values are silently treated as "unknown". ASCII strings will never be marked with a declared encoding, since their representation is the same in all supported encodings. Strings marked as "bytes" are intended to be non-ASCII strings which should be manipulated as bytes, and never converted to a character encoding (so writing them to a text file is supported only by `writeLines(useBytes = TRUE)`).

`enc2native` and `enc2utf8` convert elements of character vectors to the native encoding or UTF-8 respectively, taking any marked encoding into account. They are primitive functions, designed to do minimal copying.

There are other ways for character strings to acquire a declared encoding apart from explicitly setting it (and these have changed as R has evolved). Functions `scan`, `read.table`, `readLines`, `readLines`,...
and `parse` have an encoding argument that is used to declare encodings. `iconv` declares encodings from its `to` argument, and console input in suitable locales is also declared. `intToUtf8` declares its output as "UTF-8", and output text connections (see `textConnection`) are marked if running in a suitable locale. Under some circumstances (see its help page) `source(encoding=)` will mark encodings of character strings it outputs.

Most character manipulation functions will set the encoding on output strings if it was declared on the corresponding input. These include `chartr`, `strsplit(useBytes = FALSE)`, `tolower` and `toupper` as well as `sub(useBytes = FALSE)` and `gsub(useBytes = FALSE)`. Note that such functions do not preserve the encoding, but if they know the input encoding and that the string has been successfully re-encoded (to the current encoding or UTF-8), they mark the output.

`substr` does preserve the encoding, and `chartr`, `tolower` and `toupper` preserve UTF-8 encoding on systems with Unicode wide characters. With their `fixed` and `perl` options, `strsplit`, `sub` and `gsub` will give a marked UTF-8 result if any of the inputs are UTF-8.

`paste` and `sprintf` return elements marked as bytes if any of the corresponding inputs is marked as bytes, and otherwise marked as UTF-8 of any of the inputs is marked as UTF-8.

`match`, `pmatch`, `charmatch`, `duplicated` and `unique` all match in UTF-8 if any of the elements are marked as UTF-8.

There is some ambiguity as to what is meant by a ‘Latin-1’ locale, since some OSes (notably Windows) make use of character positions used for control characters in the ISO 8859-1 character set. How such characters are interpreted is system-dependent but as from R 3.5.0 they are if possible interpreted as per Windows codepage 1252 (which Microsoft calls ‘Windows Latin 1 (ANSI)’) when converting to e.g. UTF-8.

**Value**

A character vector.

For `enc2utf8` encodings are always marked: they are for `enc2native` in UTF-8 and Latin-1 locales.

**Examples**

```r
## x is intended to be in latin1
x <- "fa\xE7ile"
Encoding(x)
Encoding(x) <- "latin1"
x
xx <- iconv(x, "latin1", "UTF-8")
Encoding(c(x, xx))
c(x, xx)
Encoding(xx) <- "bytes"
x x will be encoded in hex
cat("xx = ", xx, "\n", sep = ")
```

### environment

**Environment Access**

Get, set, test for and create environments.
Usage

environment(fun = NULL)
environment(fun) <- value

is.environment(x)

.env
globalenv()

.env

eemptyenv()

baseenv()

new.env(hash = TRUE, parent = parent.frame(), size = 29L)

parent.env(env)

eparent.env(env) <- value

environmentName(env)

eenv.profile(env)

Arguments

fun        a function, a formula, or NULL, which is the default.
value      an environment to associate with the function
x          an arbitrary R object.
hash       a logical, if TRUE the environment will use a hash table.
parent     an environment to be used as the enclosure of the environment created.
env        an environment
size       an integer specifying the initial size for a hashed environment. An internal default value will be used if size is NA or zero. This argument is ignored if hash is FALSE.

Details

Environments consist of a frame, or collection of named objects, and a pointer to an enclosing environment. The most common example is the frame of variables local to a function call; its enclosure is the environment where the function was defined (unless changed subsequently). The enclosing environment is distinguished from the parent frame: the latter (returned by parent.frame) refers to the environment of the caller of a function. Since confusion is so easy, it is best never to use ‘parent’ in connection with an environment (despite the presence of the function parent.env).

When get or exists search an environment with the default inherits = TRUE, they look for the variable in the frame, then in the enclosing frame, and so on.

The global environment .GlobalEnv, more often known as the user’s workspace, is the first item on the search path. It can also be accessed by globalenv(). On the search path, each item’s enclosure is the next item.

The object .BaseNamespaceEnv is the namespace environment for the base package. The environment of the base package itself is available as baseenv().
If one follows the chain of enclosures found by repeatedly calling `parent.env` from any environment, eventually one reaches the empty environment `emptyenv()`, into which nothing may be assigned.

The replacement function `parent.env<-` is extremely dangerous as it can be used to destructively change environments in ways that violate assumptions made by the internal C code. It may be removed in the near future.

The replacement form of environment, `is.environment`, `baseenv`, `emptyenv` and `globalenv` are primitive functions.

System environments, such as the base, global and empty environments, have names as do the package and namespace environments and those generated by `attach()`. Other environments can be named by giving a "name" attribute, but this needs to be done with care as environments have unusual copying semantics.

**Value**

If `fun` is a function or a formula then `environment(fun)` returns the environment associated with that function or formula. If `fun` is `NULL` then the current evaluation environment is returned.

The replacement form sets the environment of the function or formula `fun` to the value given.

`is.environment(obj)` returns `TRUE` if and only if `obj` is an environment.

`new.env` returns a new (empty) environment with (by default) enclosure the parent frame.

`parent.env<-` sets the enclosing environment of its argument.

`environmentName` returns a character string, that given when the environment is printed or `""` if it is not a named environment.

`env.profile` returns a list with the following components: `size` the number of chains that can be stored in the hash table, `nchains` the number of non-empty chains in the table (as reported by `HASHPRI`), and `counts` an integer vector giving the length of each chain (zero for empty chains).

This function is intended to assess the performance of hashed environments. When `env` is a non-hashed environment, `NULL` is returned.

**See Also**

The `envir` argument of `eval`, `get`, and `exists`.

`ls` may be used to view the objects in an environment, and hence `ls.str` may be useful for an overview.

`sys.source` can be used to populate an environment.

**Examples**

```r
f <- function() "top level function"

##-- all three give the same:
environment()
environment(f)
.GlobalEnv

ls(envir = environment(stats::approxfun(1:2, 1:2, method = "const")))
```
EnvVar

Environment Variables

Description

Details of some of the environment variables which affect an R session.

Details

It is impossible to list all the environment variables which can affect an R session: some affect the OS system functions which R uses, and others will affect add-on packages. But here are notes on some of the more important ones. Those that set the defaults for options are consulted only at startup (as are some of the others).

HOME: The user’s ‘home’ directory.

LANGUAGE: Optional. The language(s) to be used for message translations. This is consulted when needed.

LC_ALL: (etc) Optional. Use to set various aspects of the locale – see Sys.getlocale. Consulted at startup.

MAKEINDEX: The path to makeindex. If unset to a value determined when R was built. Used by the emulation mode of \texttt{texi2dvi} and \texttt{texi2pdf}.

R_BATCH: Optional – set in a batch session, that is one started by R CMD BATCH. Most often set to "", so test by something like \texttt{!is.na(Sys.getenv("R\_BATCH",NA)).}

R_BROWSER: The path to the default browser. Used to set the default value of \texttt{options("browser").}

R_COMPLETION: Optional. If set to FALSE, command-line completion is not used. (Not used by the macOS GUI)

R_DEFAULT_PACKAGES: A comma-separated list of packages which are to be attached in every session. See \texttt{options}.

R_DOC_DIR: The location of the R ‘doc’ directory. Set by R.

R_ENVIRON: Optional. The path to the site environment file: see Startup. Consulted at startup.

R_GSCMD: Optional. The path to Ghostscript, used by \texttt{dev2bitmap, bitmap} and \texttt{embedFonts}. Consulted when those functions are invoked. Since it will be treated as if passed to \texttt{system}, spaces and shell metacharacters should be escaped.

R_HISTFILE: Optional. The path of the history file: see Startup. Consulted at startup and when the history is saved.
R_HISTSIZE: Optional. The maximum size of the history file, in lines. Exactly how this is used depends on the interface. For the readline command-line interface it takes effect when the history is saved (by `savehistory` or at the end of a session).

R_HOME: The top-level directory of the R installation: see `R.home`. Set by R.

R_INCLUDE_DIR: The location of the R ‘include’ directory. Set by R.

R_LIBS: Optional. Used for initial setting of `.libPaths`.

R_LIBS_SITE: Optional. Used for initial setting of `.libPaths`.

R_LIBS_USER: Optional. Used for initial setting of `.libPaths`.

R_PAPERSIZE: Optional. Used to set the default for `options("papersize")`, e.g. used by `pdf` and `postscript`.

R_PCRE_JIT_STACK_MAXSIZE: Optional. Consulted when PCRE’s JIT pattern compiler is first used. See `grep`.

R_PDFVIEWER: The path to the default PDF viewer. Used by `R CMD Rd2pdf`.

R_PLATFORM: The platform – a string of the form `cpu-vendor-os`, see `R.Version`.

R_PROFILE: Optional. The path to the site profile file: see Startup. Consulted at startup.

R_RD4PDF: Options for pdflatex processing of Rd files. Used by `R CMD Rd2pdf`.

R_SHARE_DIR: The location of the R ‘share’ directory. Set by R.

R_TEXI2DVICMD: The path to texi2dvi. Defaults to the value of `TEXI2DVI`, and if that is unset to a value determined when R was built. Consulted at startup to set the default for `options("texi2dvi")`, used by `texi2dvi` and `texi2pdf` in package `tools`.

R_UNZIPCMD: The path to unzip. Sets the initial value for `options("unzip")` on a Unix-alike when namespace `utils` is loaded.

R_ZIPCMD: The path to zip. Used by `zip` and by `R CMD INSTALL --build` on Windows.

R_UNZIPCMD, TMPDIR, TMP, TEMP: Consulted (in that order) when setting the temporary directory for the session: see `tempdir`. TMPDIR is also used by some of the utilities see the help for `build`.

TZ: Optional. The current time zone. See `Sys.timezone` for the system-specific formats. Consulted as needed.

no_proxy, http_proxy, ftp_proxy: (and more). Optional. Settings for `download.file`: see its help for further details.

Unix-specific

Some variables set on Unix-alikes, and not (in general) on Windows.

DISPLAY: Optional: used by `X11`. Tk (in package `tcltk`), the data editor and various packages.

EDITOR: The path to the default editor: sets the default for `options("editor")` when namespace `utils` is loaded.

PAGER: The path to the pager with the default setting of `options("pager")`. The default value is chosen at configuration, usually as the path to `less`.

R_PRINTCMD: Sets the default for `options("printcmd")`, which sets the default print command to be used by `postscript`.

R_SUPPORT_OLD_TARS: logical. Sets the default for the `support_old_tars` argument of `untar`. Should be set to `TRUE` if an old system tar command is used which does not support either xz compression or automatically detecting compression type.

See Also

`Sys.getenv` and `Sys.setenv` to read and set environmental variables in an R session.

`gctorture` for environment variables controlling garbage collection.
**Description**

Evaluate an R expression in a specified environment.

**Usage**

```r
eval(expr, envir = parent.frame(),
     enclos = if(is.list(envir) || is.pairlist(envir))
               parent.frame() else baseenv())
evalq(expr, envir, enclos)
eval.parent(expr, n = 1)
local(expr, envir = new.env())
```

**Arguments**

- `expr` an object to be evaluated. See ‘Details’.
- `envir` the environment in which `expr` is to be evaluated. May also be NULL, a list, a data frame, a pairlist or an integer as specified to `sys.call`.
- `enclos` Relevant when `envir` is a (pair)list or a data frame. Specifies the enclosure, i.e., where R looks for objects not found in `envir`. This can be NULL (interpreted as the base package environment, `baseenv()`) or an environment.
- `n` number of parent generations to go back

**Details**

eval evaluates the `expr` argument in the environment specified by `envir` and returns the computed value. If `envir` is not specified, then the default is `parent.frame()` (the environment where the call to `eval` was made).

Objects to be evaluated can be of types call or expression or name (when the name is looked up in the current scope and its binding is evaluated), a promise or any of the basic types such as vectors, functions and environments (which are returned unchanged).

The `evalq` form is equivalent to `eval(quote(expr),...)`. `eval` evaluates its first argument in the current scope before passing it to the evaluator: `evalq` avoids this.

`eval.parent(expr,n)` is a shorthand for `eval(expr,parent.frame(n))`.

If `envir` is a list (such as a data frame or pairlist, it is copied into a temporary environment (with enclosure `enclos`), and the temporary environment is used for evaluation. So if `expr` changes any of the components named in the (pair)list, the changes are lost.

If `envir` is NULL it is interpreted as an empty list so no values could be found in `envir` and look-up goes directly to `enclos`.

`local` evaluates an expression in a local environment. It is equivalent to `evalq` except that its default argument creates a new, empty environment. This is useful to create anonymous recursive functions and as a kind of limited namespace feature since variables defined in the environment are not visible from the outside.
Value
The result of evaluating the object: for an expression vector this is the result of evaluating the last element.

Note
Due to the difference in scoping rules, there are some differences between R and S in this area. In particular, the default enclosure in S is the global environment.

When evaluating expressions in a data frame that has been passed as an argument to a function, the relevant enclosure is often the caller’s environment, i.e., one needs `eval(x, data, parent.frame())`.

References

See Also
`expression`, `quote`, `sys.frame`, `parent.frame`, `environment`.

Further, `force` to force evaluation, typically of function arguments.

Examples
```r
eval(2 ^ 2 ^ 3)
mEx <- expression(2^2^3); mEx; 1 + eval(mEx)
eval({ xx <- pi; xx^2}); xx

a <- 3; aa <- 4; evalq(evalq(a+b+aa, list(a = 1)), list(b = 5)) # == 10
a <- 3; aa <- 4; evalq(evalq(a+b+aa, -1), list(b = 5)) # == 12

ev <- function() {
  e1 <- parent.frame()
  ## Evaluate a in e1
  aa <- eval(expression(a), e1)
  ## evaluate the expression bound to a in e1
  a <- expression(x+y)
  list(aa = aa, eval = eval(a, e1))
}
tst.ev <- function(a = 7) { x <- pi; y <- 1; ev() }
tst.ev() #-> aa : 7, eval : 4.14

a <- list(a = 3, b = 4)
with(a, a <- 5) # alters the copy of a from the list, discarded.

# Example of evalq()

N <- 3
env <- new.env()
assign("N", 27, envir = env)
# this version changes the visible copy of N only, since the argument
# passed to eval is '4'.
 eval(N <- 4, env)
```
N
get("N", envir = env)
## this version does the assignment in env, and changes N only there.
evalq(N <- 5, env)
N
get("N", envir = env)

## Uses of local()

# Mutually recursive.
# gg gets value of last assignment, an anonymous version of f.

gg <- local({
  k <- function(y)f(y)
  f <- function(x) if(x) x*k(x-1) else 1
})
gg(10)
sapply(1:5, gg)

# Nesting locals: a is private storage accessible to k
gg <- local({
  k <- local({
    a <- 1
    function(y){print(a <<- a+1);f(y)}
  })
  f <- function(x) if(x) x*k(x-1) else 1
})
sapply(1:5, gg)

ls(envir = environment(gg))
ls(envir = environment(get("k", envir = environment(gg))))

---

exists

Is an Object Defined?

Description

Look for an R object of the given name and possibly return it

Usage

exists(x, where = -1, envir = , frame, mode = "any",
       inherits = TRUE)

get0(x, envir = pos.to.env(-1L), mode = "any", inherits = TRUE,
     ifnotfound = NULL)

Arguments

x
  a variable name (given as a character string or a symbol).
The `exists` function can specify the environment in which to look for the object in any of several ways: as an integer (the position in the search list); as the character string name of an element in the search list; or as an environment (including using `sys.frame` to access the currently active function calls). The `envir` argument is an alternative way to specify an environment, but is primarily there for backward compatibility.

This function looks to see if the name `x` has a value bound to it in the specified environment. If `inherits` is `TRUE` and a value is not found for `x` in the specified environment, the enclosing frames of the environment are searched until the name `x` is encountered. See `environment` and the ‘R Language Definition’ manual for details about the structure of environments and their enclosures.

**Warning:** `inherits = TRUE` is the default behaviour for R but not for S.

If `mode` is specified then only objects of that type are sought. The `mode` may specify one of the collections "numeric" and "function" (see `mode`): any member of the collection will suffice. (This is true even if a member of a collection is specified, so for example `mode = "special"` will seek any type of function.)

**Value**

- `exists()`: Logical, true if and only if an object of the correct name and mode is found.
- `get0()`: The object—as from `get(x,*)`—if `exists(x,*)` is true, otherwise `ifnotfound`.

**Note**

With `get0()`, instead of the easy to read but somewhat inefficient

```r
if (exists(myVarName, envir = myEnvir)) {
  r <- get(myVarName, envir = myEnvir)
  ## ... deal with r ...
}
```

you now can use the more efficient (and slightly harder to read)

```r
if (!is.null(r <- get0(myVarName, envir = myEnvir))) {
  ## ... deal with r ...
}
```

**References**

See Also

get and hasName. For quite a different kind of “existence” checking, namely if function arguments
were specified, missing; and for yet a different kind, namely if a file exists, file.exists.

Examples

## Define a substitute function if necessary:
if(!exists("some.fun", mode = "function"))
  some.fun <- function(x) { cat("some.fun(x)\n"); x }
search()
exists("ls", 2) # true even though ls is in pos = 3
exists("ls", 2, inherits = FALSE) # false

## These are true (in most circumstances):
identical(ls, get0("ls"))
identical(NULL, get0(".foo.bar.")) # default ifnotfound = NULL (!)

---

**expand.grid**

Create a Data Frame from All Combinations of Factor Variables

Description

Create a data frame from all combinations of the supplied vectors or factors. See the description of
the return value for precise details of the way this is done.

Usage

expand.grid(..., KEEP.OUT.ATTRS = TRUE, stringsAsFactors = TRUE)

Arguments

... vectors, factors or a list containing these.
KEEP.OUT.ATTRS a logical indicating the "out.attrs" attribute (see below) should be computed
and returned.
stringsAsFactors logical specifying if character vectors are converted to factors.

Value

A data frame containing one row for each combination of the supplied factors. The first factors vary
fastest. The columns are labelled by the factors if these are supplied as named arguments or named
components of a list. The row names are ‘automatic’.

Attribute "out.attrs" is a list which gives the dimension and dimnames for use by predict
methods.

Note

Conversion to a factor is done with levels in the order they occur in the character vectors (and not
alphabetically, as is most common when converting to factors).
expression

References

combn (package utils) for the generation of all combinations of n elements, taken m at a time.

Examples

```r
require(utils)

expand.grid(height = seq(60, 80, 5), weight = seq(100, 300, 50),
            sex = c("Male","Female"))

x <- seq(0, 10, length.out = 100)
y <- seq(-1, 1, length.out = 20)
d1 <- expand.grid(x = x, y = y)
d2 <- expand.grid(x = x, y = y, KEEP.OUT.ATTRS = FALSE)
object.size(d1) - object.size(d2)
##-> 5992 or 8832 (on 32- / 64-bit platform)
```

---

expression Unevaluated Expressions

Description

Creates or tests for objects of mode "expression".

Usage

expression(...)

is.expression(x)
as.expression(x, ...)

Arguments

... expression: R objects, typically calls, symbols or constants.
as.expression: arguments to be passed to methods.
x an arbitrary R object.

Details

‘Expression’ here is not being used in its colloquial sense, that of mathematical expressions. Those are calls (see call) in R, and an R expression vector is a list of calls, symbols etc, for example as returned by parse.

As an object of mode "expression" is a list, it can be subsetted by [, [[ or $, the latter two extracting individual calls etc. The replacement forms of these operators can be used to replace or delete elements.

evaluation and is.expression are primitive functions. expression is ‘special’: it does not evaluate its arguments.
Extract

Value

expression returns a vector of type "expression" containing its arguments (unevaluated).
is.expression returns TRUE if expr is an expression object and FALSE otherwise.
as.expression attempts to coerce its argument into an expression object. It is generic, and only
the default method is described here. (The default method calls as.vector(type = "expression")
and so may dispatch methods for as.vector.) NULL, calls, symbols (see as.symbol) and pairlists
are returned as the element of a length-one expression vector. Atomic vectors are placed element-
by-element into an expression vector (without using any names): lists are changed type to an ex-
pression vector (keeping all attributes). Other types are not currently supported.

References

ex1
eval(ex1) # 1:10

length(ex3 <- expression(u, 2, u + 0:9)) # 3
mode(ex3 [3]) # expression
mode(ex3[[3]]) # call
## but not all components are 'call's :
sapply(ex3, mode ) # name numeric call
sapply(ex3, typeof) # symbol double language
rm(ex3)

Extract

Extract or Replace Parts of an Object

Description

Operators acting on vectors, matrices, arrays and lists to extract or replace parts.

Usage

x[i]
x[i, ... , drop = TRUE]
x[[i], exact = TRUE]]
x[[i, j, ... , exact = TRUE]]
x$name
ggetElement(object, name)

x[i] <- value
x[i, j, ... ] <- value
x[[i]] <- value
x$name <- value
Arguments

x, object  object from which to extract element(s) or in which to replace element(s).
i, j, ...  indices specifying elements to extract or replace. Indices are numeric or character vectors or empty (missing) or NULL. Numeric values are coerced to integer as by as.integer (and hence truncated towards zero). Character vectors will be matched to the names of the object (or for matrices/arrays, the dimnames): see ‘Character indices’ below for further details.

For [ indexing only: i, j, ... can be logical vectors, indicating elements/slices to select. Such vectors are recycled if necessary to match the corresponding extent. i, j, ... can also be negative integers, indicating elements/slices to leave out of the selection.

When indexing arrays by [ a single argument i can be a matrix with as many columns as there are dimensions of x; the result is then a vector with elements corresponding to the sets of indices in each row of i.

An index value of NULL is treated as if it were integer(0).

name  A literal character string or a name (possibly backtick quoted). For extraction, this is normally (see under ‘Environments’) partially matched to the names of the object.

drop  For matrices and arrays. If TRUE the result is coerced to the lowest possible dimension (see the examples). This only works for extracting elements, not for the replacement. See drop for further details.

exact  Controls possible partial matching of [[ when extracting by a character vector (for most objects, but see under ‘Environments’). The default is no partial matching. Value NA allows partial matching but issues a warning when it occurs. Value FALSE allows partial matching without any warning.

value  typically an array-like R object of a similar class as x.

Details

These operators are generic. You can write methods to handle indexing of specific classes of objects, see InternalMethods as well as [.data.frame and [.factor. The descriptions here apply only to the default methods. Note that separate methods are required for the replacement functions [<-, [[<- and $<- for use when indexing occurs on the assignment side of an expression.

The most important distinction between [, [[ and $ is that the [ can select more than one element whereas the other two select a single element.

The default methods work somewhat differently for atomic vectors, matrices/arrays and for recursive (list-like, see is.recursive) objects. $ is only valid for recursive objects, and is only discussed in the section below on recursive objects.

Subsetting (except by an empty index) will drop all attributes except names, dim and dimnames.

Indexing can occur on the right-hand-side of an expression for extraction, or on the left-hand-side for replacement. When an index expression appears on the left side of an assignment (known as subassignment) then that part of x is set to the value of the right hand side of the assignment. In this case no partial matching of character indices is done, and the left-hand-side is coerced as needed to accept the values. For vectors, the answer will be of the higher of the types of x and value in the hierarchy raw < logical < integer < double < complex < character < list < expression. Attributes are preserved (although names, dim and dimnames will be adjusted suitably). Subassignment is done sequentially, so if an index is specified more than once the latest assigned value for an index will result.

It is an error to apply any of these operators to an object which is not subsettable (e.g., a function).
Atomic vectors

The usual form of indexing is `[]`. `[[` can be used to select a single element *dropping names*, whereas `[` keeps them, e.g., in `c(abc = 123)[1]`.

The index object `i` can be numeric, logical, character or empty. Indexing by factors is allowed and is equivalent to indexing by the numeric codes (see `factor`) and not by the character values which are printed (for which use `[as.character(i)]`).

An empty index selects all values: this is most often used to replace all the entries but keep the attributes.

Matrices and arrays

Matrices and arrays are vectors with a dimension attribute and so all the vector forms of indexing can be used with a single index. The result will be an unnamed vector unless `x` is one-dimensional when it will be a one-dimensional array.

The most common form of indexing a `k`-dimensional array is to specify `k` indices to `[`. As for vector indexing, the indices can be numeric, logical, character, empty or even factor. And again, indexing by factors is equivalent to indexing by the numeric codes, see ‘Atomic vectors’ above.

An empty index (a comma separated blank) indicates that all entries in that dimension are selected. The argument `drop` applies to this form of indexing.

A third form of indexing is via a numeric matrix with the one column for each dimension: each row of the index matrix then selects a single element of the array, and the result is a vector. Negative indices are not allowed in the index matrix. `NA` and zero values are allowed: rows of an index matrix containing a zero are ignored, whereas rows containing an `NA` produce an `NA` in the result.

Indexing via a character matrix with one column per dimensions is also supported if the array has dimension names. As with numeric matrix indexing, each row of the index matrix selects a single element of the array. Indices are matched against the appropriate dimension names. `NA` is allowed and will produce an `NA` in the result. Unmatched indices as well as the empty string (“”) are not allowed and will result in an error.

A vector obtained by matrix indexing will be unnamed unless `x` is one-dimensional when the row names (if any) will be indexed to provide names for the result.

Recursive (list-like) objects

Indexing by `[]` is similar to atomic vectors and selects a list of the specified element(s).

Both `[]` and `$` select a single element of the list. The main difference is that `$` does not allow computed indices, whereas `[]` does. `x$name` is equivalent to `x[['name',exact = FALSE]]`. Also, the partial matching behavior of `[]` can be controlled using the `exact` argument.

getElement(x, name) is a version of `x[['name',exact = TRUE]]` which for formally classed (S4) objects returns `slot(x,name)`, hence providing access to even more general list-like objects.

`[]` and `[[` are sometimes applied to other recursive objects such as calls and expressions. Pairlists are coerced to lists for extraction by `[]`, but all three operators can be used for replacement.

`[[` can be applied recursively to lists, so that if the single index `i` is a vector of length `p`, `alist[[i]]` is equivalent to `alist[[i1]][[i2]]...[[ip]]` providing all but the final indexing results in a list.

Note that in all three kinds of replacement, a value of `NULL` deletes the corresponding item of the list. To set entries to `NULL`, you need `x[i] <- list(NULL)`.

When `$<-` is applied to a `NULL x`, it first coerces `x` to `list()`. This is what also happens with `[[<-` where in R versions less than 4.y.z, a length one value resulted in a length one (atomic) vector.
Environments

Both $ and [[ can be applied to environments. Only character indices are allowed and no partial matching is done. The semantics of these operations are those of get(i, env = x, inherits = FALSE). If no match is found then NULL is returned. The replacement versions, $<-$ and [[<-, can also be used. Again, only character arguments are allowed. The semantics in this case are those of assign(i, value, env = x, inherits = FALSE). Such an assignment will either create a new binding or change the existing binding in x.

NAs in indexing

When extracting, a numerical, logical or character NA index picks an unknown element and so returns NA in the corresponding element of a logical, integer, numeric, complex or character result, and NULL for a list. (It returns 00 for a raw result.) When replacing (that is using indexing on the lhs of an assignment) NA does not select any element to be replaced. As there is ambiguity as to whether an element of the rhs should be used or not, this is only allowed if the rhs value is of length one (so the two interpretations would have the same outcome). (The documented behaviour of S was that an NA replacement index ‘goes nowhere’ but uses up an element of value: Becker et al p. 359. However, that has not been true of other implementations.)

Argument matching

Note that these operations do not match their index arguments in the standard way: argument names are ignored and positional matching only is used. So m[j = 2, i = 1] is equivalent to m[2,1] and not to m[1,2].

This may not be true for methods defined for them; for example it is not true for the data.frame methods described in [.data.frame which warn if i or j is named and have undocumented behaviour in that case.

To avoid confusion, do not name index arguments (but drop and exact must be named).

S4 methods

These operators are also implicit S4 generics, but as primitives, S4 methods will be dispatched only on S4 objects x.

The implicit generics for the $ and $<-$ operators do not have name in their signature because the grammar only allows symbols or string constants for the name argument.

Character indices

Character indices can in some circumstances be partially matched (see pmatch) to the names or dimnames of the object being subsetted (but never for subassignment). Unlike S (Becker et al p. 358), R never uses partial matching when extracting by [, and partial matching is not by default used by [[ (see argument exact).

Thus the default behaviour is to use partial matching only when extracting from recursive objects (except environments) by $. Even in that case, warnings can be switched on by options(warnPartialMatchDollar = TRUE).

Neither empty ("") nor NA indices match any names, not even empty nor missing names. If any object has no names or appropriate dimnames, they are taken as all "" and so match nothing.

Examples

```r
x <- 1:12
m <- matrix(1:6, nrow = 2, dimnames = list(c("a", "b"), LETTERS[1:3]))
li <- list(pi = pi, e = exp(1))
x[10]  # the tenth element of x
x <- x[-1]  # delete the 1st element of x
m[,]  # the first row of matrix m
m[, , drop = FALSE]  # is a 1-row matrix
m[cbind(c(1,2,1),3:1)]  # matrix numeric index
 ci <- cbind(c("a", "b", "a"), c("A", "C", "B"))
m[ci]  # matrix character index
m <- m[,-1]  # delete the first column of m
li[[1]]  # the first element of list li
y <- list(1, 2, a = 4, 5)
y[c(3, 4)]  # a list containing elements 3 and 4 of y
y$a  # the element of y named a
```

## non-integer indices are truncated:
(i <- 3.999999999)  # "4" is printed
(1:5)[i]  # 3

## named atomic vectors, compare "[" and "[[":
nx <- c(Abc = 123, pi = pi)
nx[1] ; nx["pi"]  # keeps names, whereas "[" does not:
nx[[1]] ; nx[["pi"]]

## recursive indexing into lists
z <- list(a = list(b = 9, c = "hello"), d = 1:5)
unlist(z)
z[[c(1, 2)]]
z[[c(1, 2, 1)]]  # both "hello"
z[[c("a", "b")]]  # "new"
unlist(z)

## check $ and [[ for environments
e1 <- new.env()
e1$a <- 10
e1[["a"]]
e1[["b"]]<- 20
e1$b
```
ls(e1)

## partial matching - possibly with warning :
stopifnot(identical(li$p, pi))
op <- options(warnPartialMatchDollar = TRUE)
stopifnot( identical(li$p, pi), #-- a warning
  inherits(tryCatch (li$p, warning = identity), "warning"))
## revert the warning option:
if(is.null(op[[1]])) op[[1]] <- FALSE; options(op)

---

#### Extract.data.frame

**Extract or Replace Parts of a Data Frame**

**Description**

Extract or replace subsets of data frames.

**Usage**

```r
## S3 method for class 'data.frame'
x[i, j, drop = ]
## S3 replacement method for class 'data.frame'
x[i, j] <- value
## S3 method for class 'data.frame'
x[[..., exact = TRUE]]
## S3 replacement method for class 'data.frame'
x[[i, j]] <- value
## S3 replacement method for class 'data.frame'
x$name <- value
```

**Arguments**

- `x` data frame.
- `i, j, ...` elements to extract or replace. For `[` and `[[`, these are numeric or character or, for `[` only, empty or logical. Numeric values are coerced to integer as if by `as.integer`. For replacement by `[`, a logical matrix is allowed.
- `name` A literal character string or a name (possibly backtick quoted).
- `drop` logical. If TRUE the result is coerced to the lowest possible dimension. The default is to drop if only one column is left, but not to drop if only one row is left.
- `value` A suitable replacement value: it will be repeated a whole number of times if necessary and it may be coerced: see the Coercion section. If NULL, deletes the column if a single column is selected.
- `exact` logical: see `[`, and applies to column names.
Details

Data frames can be indexed in several modes. When [ and [[ are used with a single vector index (x[1] or x[[1]]), they index the data frame as if it were a list. In this usage a drop argument is ignored, with a warning.

There is no data.frame method for $, so x$name uses the default method which treats x as a list (with partial matching of column names if the match is unique, see Extract). The replacement method (for $) checks value for the correct number of rows, and replicates it if necessary.

When [ and [[ are used with two indices (x[i,j] and x[[i,j]]) they act like indexing a matrix: [[ can only be used to select one element. Note that for each selected column, xj say, typically (if it is not matrix-like), the resulting column will be x[j], and hence rely on the corresponding [ method, see the examples section.

If [ returns a data frame it will have unique (and non-missing) row names, if necessary transforming the row names using make.unique. Similarly, if columns are selected column names will be transformed to be unique if necessary (e.g., if columns are selected more than once, or if more than one column of a given name is selected if the data frame has duplicate column names).

When drop = TRUE, this is applied to the subsetting of any matrices contained in the data frame as well as to the data frame itself.

The replacement methods can be used to add whole column(s) by specifying non-existent column(s), in which case the column(s) are added at the right-hand edge of the data frame and numerical indices must be contiguous to existing indices. On the other hand, rows can be added at any row after the current last row, and the columns will be in-filled with missing values. Missing values in the indices are not allowed for replacement.

For [ the replacement value can be a list: each element of the list is used to replace (part of) one column, recycling the list as necessary. If columns specified by number are created, the names (if any) of the corresponding list elements are used to name the columns. If the replacement is not selecting rows, list values can contain NULL elements which will cause the corresponding columns to be deleted. (See the Examples.)

Matrix indexing (x[i] with a logical or a 2-column integer matrix i) using [ is not recommended. For extraction, x is first coerced to a matrix. For replacement, logical matrix indices must be of the same dimension as x. Replacements are done one column at a time, with multiple type coercions possibly taking place.

Both [ and [[ extraction methods partially match row names. By default neither partially match column names, but [[ will if exact = FALSE (and with a warning if exact = NA). If you want to exact matching on row names use match, as in the examples.

Value

For [ a data frame, list or a single column (the latter two only when dimensions have been dropped). If matrix indexing is used for extraction a vector results. If the result would be a data frame an error results if undefined columns are selected (as there is no general concept of a ‘missing’ column in a data frame). Otherwise if a single column is selected and this is undefined the result is NULL.

For [[ a column of the data frame or NULL (extraction with one index) or a length-one vector (extraction with two indices).

For $, a column of the data frame (or NULL).

For [<-, [[<-, and $<-, a data frame.
Coercion

The story over when replacement values are coerced is a complicated one, and one that has changed during R's development. This section is a guide only.

When `[]` and `[[` are used to add or replace a whole column, no coercion takes place but `value` will be replicated (by calling the generic function `rep`) to the right length if an exact number of repeats can be used.

When `[]` is used with a logical matrix, each value is coerced to the type of the column into which it is to be placed.

When `[]` and `[[` are used with two indices, the column will be coerced as necessary to accommodate the value.

Note that when the replacement value is an array (including a matrix) it is not treated as a series of columns (as `data.frame` and `as.data.frame` do) but inserted as a single column.

Warning

The default behaviour when only one row is left is equivalent to specifying `drop = FALSE`. To drop from a data frame to a list, `drop = TRUE` has to be specified explicitly.

Arguments other than `drop` and `exact` should not be named: there is a warning if they are and the behaviour differs from the description here.

See Also

`subset` which is often easier for extraction, `data.frame`, `Extract`.

Examples

```r
sw <- swiss[1:5, 1:4] # select a manageable subset
sw[1:3] # select columns
sw[, 1:3] # same
sw[4:5, 1:3] # select rows and columns
sw[1] # a one-column data frame
sw[, 1, drop = FALSE] # the same
sw[, 1] # a (unnamed) vector
sw[[1]] # the same
sw$Fert # the same (possibly w/ warning, see ?Extract)
sw[1,] # a one-row data frame
sw[1,, drop = TRUE] # a list
sw["C", ] # partially matches
sw[match("C", row.names(sw)), ] # no exact match
try(sw[,"Ferti"]) # column names must match exactly

sw[sw$Fertility > 90,] # logical indexing, see also ?subset
sw[cc(1, 1:2), ] # duplicate row, unique row names are created

sw[sw <= 6] <- 6 # logical matrix indexing
sw

## adding a column
sw["new1"] <- LETTERS[1:5] # adds a character column
```
sw["new2"] <- letters[1:5] # ditto
sw[, "new3"] <- LETTERS[1:5] # ditto
sw$new4 <- 1:5
sapply(sw, class)
sw$new # -> NULL: no unique partial match
sw$new4 <- NULL # delete the column
sw
sw[6:8] <- list(letters[10:14], NULL, aa = 1:5)
# update col. 6, delete 7, append
sw

## matrices in a data frame
A <- data.frame(x = 1:3, y = I(matrix(4:9, 3, 2)),
                 z = I(matrix(letters[1:9], 3, 3)))
A[1:3, "y"] # a matrix
A[1:3, "z"] # a matrix
A[, "y"] # a matrix
stopifnot(identical(colnames(A), c("x", "y", "z")),
           ncol(A) == 3L,
           identical(A[,"y"], A[1:3, "y"]),
           inherits(A[,"y"], "AsIs"))

## keeping special attributes: use a class with a
## "as.data.frame" and "[" method;
## "avector" := vector that keeps attributes. Could provide a constructor
## avector <- function(x) { class(x) <- c("avector", class(x)); x }
## as.data.frame.avector <- as.data.frame.vector
`[.avector` <- function(x,i,...) {
  r <- NextMethod("[")
  mostattributes(r) <- attributes(x)
  r
}

d <- data.frame(i = 0:7, f = gl(2,4),
                 u = structure(11:18, unit = "kg", class = "avector"))
str(d[2:4, -1]) # 'u' keeps its "unit"

Extract or Replace Parts of a Factor

Description

Extract or replace subsets of factors.

Usage

## S3 method for class 'factor'
x[[...], drop = FALSE]
## S3 method for class 'factor'
x[[...]]
## S3 replacement method for class 'factor'
x[[...]] <- value
## S3 replacement method for class 'factor'
x[[...]] <- value
Arguments

x  a factor
... a specification of indices – see Extract.
drop  logical. If true, unused levels are dropped.
value  character: a set of levels. Factor values are coerced to character.

Details

When unused levels are dropped the ordering of the remaining levels is preserved.
If value is not in levels(x), a missing value is assigned with a warning.
Any contrasts assigned to the factor are preserved unless drop = TRUE.
The [[ method supports argument exact.

Value

A factor with the same set of levels as x unless drop = TRUE.

See Also

factor, Extract.

Examples

## following example(factor)
(ff <- factor(substring("statistics", 1:10, 1:10), levels = letters))
ff[, drop = TRUE]
factor(letters[7:10])[2:3, drop = TRUE]

Maxima and Minima

Description

Returns the (regular or parallel) maxima and minima of the input values.
pmax*() and pmin*() take one or more vectors as arguments, recycle them to common length and return a single vector giving the ‘parallel’ maxima (or minima) of the argument vectors.

Usage

max(..., na.rm = FALSE)
min(..., na.rm = FALSE)
pmax(..., na.rm = FALSE)
pmin(..., na.rm = FALSE)
pmax.int(..., na.rm = FALSE)
pmin.int(..., na.rm = FALSE)
Arguments

... numeric or character arguments (see Note).

na.rm a logical indicating whether missing values should be removed.

Details

\texttt{max} and \texttt{min} return the maximum or minimum of all the values present in their arguments, as \texttt{integer} if all are \texttt{logical} or \texttt{integer}, as \texttt{double} if all are numeric, and character otherwise.

If \texttt{na.rm} is \texttt{FALSE} an NA value in any of the arguments will cause a value of \texttt{NA} to be returned, otherwise \texttt{NA} values are ignored.

The minimum and maximum of a numeric empty set are +\texttt{Inf} and -\texttt{Inf} (in this order!) which ensures \textit{transitivity}, e.g., \texttt{min(x1,min(x2)) == min(x1,x2)}. For numeric \texttt{x max(x) == -\texttt{Inf} and min(x) == +\texttt{Inf} whenever length(x) == 0} (after removing missing values if requested). However, \texttt{pmax} and \texttt{pmin} return \texttt{NA} if all the parallel elements are \texttt{NA} even for \texttt{na.rm = TRUE}.

\texttt{pmax} and \texttt{pmin} take one or more vectors (or matrices) as arguments and return a single vector giving the ‘parallel’ maxima (or minima) of the vectors. The first element of the result is the maximum (minimum) of the first elements of all the arguments, the second element of the result is the maximum (minimum) of the second elements of all the arguments and so on. Shorter inputs (of non-zero length) are recycled if necessary. Attributes (see \texttt{attributes}: such as \texttt{names} or \texttt{dim}) are copied from the first argument (if applicable, e.g., \texttt{not} for an \texttt{S4} object).

\texttt{pmax.int} and \texttt{pmin.int} are faster internal versions only used when all arguments are atomic vectors and there are no classes: they drop all attributes. (Note that all versions fail for raw and complex vectors since these have no ordering.)

\texttt{max} and \texttt{min} are generic functions: methods can be defined for them individually or via the \texttt{Summary} group generic. For this to work properly, the arguments . . . should be unnamed, and dispatch is on the first argument.

By definition the min/max of a numeric vector containing an \texttt{NaN} is \texttt{NaN}, except that the min/max of any vector containing an \texttt{NA} is \texttt{NA} even if it also contains an \texttt{NaN}. Note that \texttt{max(NA,\texttt{Inf}) == NA} even though the maximum would be \texttt{Inf} whatever the missing value actually is.

Character versions are sorted lexicographically, and this depends on the collating sequence of the locale in use: the help for ‘Comparison’ gives details. The max/min of an empty character vector is defined to be character \texttt{NA}. (One could argue that as ‘’ is the smallest character element, the maximum should be ‘’), but there is no obvious candidate for the minimum.)

Value

For \texttt{min} or \texttt{max}, a length-one vector. For \texttt{pmin} or \texttt{pmax}, a vector of length the longest of the input vectors, or length zero if one of the inputs had zero length.

The type of the result will be that of the highest of the inputs in the hierarchy \texttt{integer} < \texttt{double} < character.

For \texttt{min} and \texttt{max} if there are only numeric inputs and all are empty (after possible removal of NAs), the result is double (\texttt{Inf} or \texttt{-Inf}).

S4 methods

\texttt{max} and \texttt{min} are part of the \texttt{S4 Summary} group generic. Methods for them must use the signature \texttt{x,...,na.rm}.
Note

‘Numeric’ arguments are vectors of type integer and numeric, and logical (coerced to integer). For historical reasons, NULL is accepted as equivalent to integer(0).

pmax and pmin will also work on classed S3 or S4 objects with appropriate methods for comparison, i.e., na and rep (if recycling of arguments is needed).

References

See Also

range (both min and max) and which.min (which.max) for the arg min, i.e., the location where an extreme value occurs.

‘plotmath’ for the use of min in plot annotation.

Examples

```
require(stats); require(graphics)
min(5:1, pi) #-> one number
pmin(5:1, pi) #-> 5 numbers

x <- sort(rnorm(100)); ch <- 1.35
pmin(ch, quantile(x)) # no names
pmin(quantile(x), ch) # has names
plot(x, pmin(ch, pmax(-ch, x)), type = "b", main = "Huber's function")

cut01 <- function(x) pmax(pmin(x, 1), 0)
curve(x^2 - 1/4, -1.4, 1.5, col = 2)
curve(cut01(x^2 - 1/4), col = "blue", add = TRUE, n = 500)
# pmax(), pmin() preserve attributes of *first* argument
D <- diag(x = (3:1)/4) ; n0 <- numeric()
stopifnot(identical(D, cut01(D) ),
        identical(n0, cut01(n0)),
        identical(n0, cut01(NULL)),
        identical(n0, pmax(3:1, n0, 2)),
        identical(n0, pmax(n0, 4)))
```

```
Details

The reports the versions of third-party software libraries in use. These are often external but might have been compiled into R when it was installed.

With dynamic linking, these are the versions of the libraries linked to in this session: with static linking, of those compiled in.

Value

A named character vector, currently with components

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>zlib</td>
<td>The version of zlib in use.</td>
</tr>
<tr>
<td>bzlib</td>
<td>The version of bzlib (from bzip2) in use.</td>
</tr>
<tr>
<td>xz</td>
<td>The version of libzma (from xz) in use.</td>
</tr>
<tr>
<td>PCRE</td>
<td>The version of PCRE in use. PCRE1 has versions &lt; 10.00, PCRE2 has versions &gt;= 10.00.</td>
</tr>
<tr>
<td>ICU</td>
<td>The version of ICU in use (if any, otherwise &quot;&quot;).</td>
</tr>
<tr>
<td>TRE</td>
<td>The version of libtre in use.</td>
</tr>
<tr>
<td>iconv</td>
<td>The implementation and version of the iconv library in use (if known).</td>
</tr>
<tr>
<td>readline</td>
<td>The version of readline in use (if any, otherwise &quot;). If using the emulation by libedit aka editline this will be &quot;EditLine wrapper&quot; preceded by the readline version it emulates: that is most likely to be seen on macOS.</td>
</tr>
<tr>
<td>BLAS</td>
<td>Name of the binary/executable file with the implementation of BLAS in use (if known, otherwise &quot;).</td>
</tr>
</tbody>
</table>

Note that the values for bzlib and pcre normally contain a date as well as the version number, and that for tre includes several items separated by spaces, the version number being the second.

For iconv this will give the implementation as well as the version, for example "GNU libiconv 1.14", "glibc 2.18" or "win_iconv" (which has no version number).

The name of the binary/executable file for BLAS can be used as an indication of which implementation is in use. Typically, the R version of BLAS will appear as libR.so (libR.dylib), R or libRblas.so (libRblas.dylib), depending on how R was built. Note that libRblas.so (libRblas.dylib) may also be shown for an external BLAS implementation that had been copied, hard-linked or renamed by the system administrator. For an external BLAS, a shared object file will be given and its path/name may indicate the vendor/version. The detection does not work on Windows.

factor

Factors

Description

The function factor is used to encode a vector as a factor (the terms 'category' and 'enumerated type' are also used for factors). If argument ordered is TRUE, the factor levels are assumed to be ordered. For compatibility with S there is also a function ordered.

is.factor, is.ordered, as.factor and as.ordered are the membership and coercion functions for these classes.

Usage

factor(x = character(), levels, labels = levels, exclude = NA, ordered = is.ordered(x), nmax = NA)

ordered(x, ...)

is.factor(x)

is.ordered(x)

as.factor(x)

as.ordered(x)

addNA(x, ifany = FALSE)

Arguments

x a vector of data, usually taking a small number of distinct values.

levels an optional vector of the unique values (as character strings) that x might have taken. The default is the unique set of values taken by as.character(x), sorted into increasing order of x. Note that this set can be specified as smaller than sort(unique(x)).

labels either an optional character vector of labels for the levels (in the same order as levels after removing those in exclude), or a character string of length 1. Duplicated values in labels can be used to map different values of x to the same factor level.

exclude a vector of values to be excluded when forming the set of levels. This may be factor with the same level set as x or should be a character.

ordered logical flag to determine if the levels should be regarded as ordered (in the order given).

nmax an upper bound on the number of levels; see ‘Details’.

... (in ordered(.)): any of the above, apart from ordered itself.

ifany only add an NA level if it is used, i.e. if any(is.na(x)).
Details

The type of the vector \( x \) is not restricted; it only must have an \texttt{as.character} method and be sortable (by \texttt{order}).

Ordered factors differ from factors only in their class, but methods and the model-fitting functions treat the two classes quite differently.

The encoding of the vector happens as follows. First all the values in \texttt{exclude} are removed from \texttt{levels}. If \( x[i] \) equals \texttt{levels[j]} then the \( i \)-th element of the result is \( j \). If no match is found for \( x[i] \) in \texttt{levels} (which will happen for excluded values) then the \( i \)-th element of the result is set to \texttt{NA}.

Normally the 'levels' used as an attribute of the result are the reduced set of levels after removing those in \texttt{exclude}, but this can be altered by supplying \texttt{labels}. This should either be a set of new labels for the levels, or a character string, in which case the levels are that character string with a sequence number appended.

\texttt{factor(x,exclude = NULL)} applied to a factor without \texttt{NA}s is a no-operation unless there are unused levels: in that case, a factor with the reduced level set is returned. If \texttt{exclude} is used, since R version 3.4.0, excluding non-existing character levels is equivalent to excluding nothing, and when \texttt{exclude} is a \texttt{character} vector, that is applied to the levels of \( x \). Alternatively, \texttt{exclude} can be a factor with the same level set as \( x \) and will exclude the levels present in \texttt{exclude}.

The codes of a factor may contain \texttt{NA}. For a numeric \( x \), set \texttt{exclude = NULL} to make \texttt{NA} an extra level (prints as \texttt{<NA>}); by default, this is the last level.

If \texttt{NA} is a level, the way to set a code to be missing (as opposed to the code of the missing level) is to use \texttt{is.na} on the left-hand-side of an assignment (as in \texttt{is.na(f)[i] <- TRUE}; indexing inside \texttt{is.na} does not work). Under those circumstances missing values are currently printed as \texttt{<NA>}, i.e., identical to entries of level \texttt{NA}.

\texttt{is.factor} is generic: you can write methods to handle specific classes of objects, see \texttt{Internal-Methods}.

Where \texttt{levels} is not supplied, \texttt{unique} is called. Since factors typically have quite a small number of levels, for large vectors \( x \) it is helpful to supply \texttt{nmax} as an upper bound on the number of unique values.

Since R 4.1.0, when using \texttt{c} to combine a (possibly ordered) factor with other objects, if all objects are (possibly ordered) factors, the result will be a factor with levels the union of the level sets of the elements, in the order the levels occur in the level sets of the elements (which means that if all the elements have the same level set, that is the level set of the result), equivalent to how \texttt{unlist} operates on a list of factor objects.

Value

\texttt{factor} returns an object of class "factor" which has a set of integer codes the length of \( x \) with a "levels" attribute of mode \texttt{character} and unique (!\texttt{anyDuplicated(.)}) entries. If argument \texttt{ordered} is true (or \texttt{ordered()} is used) the result has class c("ordered","factor"). Undocumentedly for a long time, \texttt{factor(x)} loses all \texttt{attributes(x)} but "names", and resets "levels" and "class".

Applying \texttt{factor} to an ordered or unordered factor returns a factor (of the same type) with just the levels which occur: see also \texttt{[.factor} for a more transparent way to achieve this.

\texttt{is.factor} returns \texttt{TRUE} or \texttt{FALSE} depending on whether its argument is of type factor or not. Correspondingly, \texttt{is.ordered} returns \texttt{TRUE} when its argument is an ordered factor and \texttt{FALSE} otherwise.

\texttt{as.factor} coerces its argument to a factor. It is an abbreviated (sometimes faster) form of \texttt{factor}.

\texttt{as.ordered(x)} returns \( x \) if this is ordered, and \texttt{ordered(x)} otherwise.
factor modifies a factor by turning NA into an extra level (so that NA values are counted in tables, for instance).

.valid.factor(object) checks the validity of a factor, currently only levels(object), and returns TRUE if it is valid, otherwise a string describing the validity problem. This function is used for validObject(<factor>).

Warning
The interpretation of a factor depends on both the codes and the "levels" attribute. Be careful only to compare factors with the same set of levels (in the same order). In particular, as.numeric applied to a factor is meaningless, and may happen by implicit coercion. To transform a factor f to approximately its original numeric values, as.numeric(levels(f))[f] is recommended and slightly more efficient than as.numeric(as.character(f)).

The levels of a factor are by default sorted, but the sort order may well depend on the locale at the time of creation, and should not be assumed to be ASCII.

There are some anomalies associated with factors that have NA as a level. It is suggested to use them sparingly, e.g., only for tabulation purposes.

Comparison operators and group generic methods

There are "factor" and "ordered" methods for the group generic Ops which provide methods for the Comparison operators, and for the min, max, and range generics in Summary of "ordered". (The rest of the groups and the Math group generate an error as they are not meaningful for factors.)

Only == and != can be used for factors: a factor can only be compared to another factor with an identical set of levels (not necessarily in the same ordering) or to a character vector. Ordered factors are compared in the same way, but the general dispatch mechanism precludes comparing ordered and unordered factors.

The levels of the operands: if both operands are ordered factors they must have the same level set.

Note
In earlier versions of R, storing character data as a factor was more space efficient if there is even a small proportion of repeats. However, identical character strings now share storage, so the difference is small in most cases. (Integer values are stored in 4 bytes whereas each reference to a character string needs a pointer of 4 or 8 bytes.)

Examples
(ff <- factor(substring("statistics", 1:10, 1:10), levels = letters))
as.integer(ff) # the internal codes
(f. <- factor(ff)) # drops the levels that do not occur
file.access

Ascertain File Accessibility

Description
Utility function to access information about files on the user’s file systems.

Usage
file.access(names, mode = 0)

Arguments

<table>
<thead>
<tr>
<th>name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>names</td>
<td>character vector containing file names. Tilde-expansion will be done: see path.expand.</td>
</tr>
<tr>
<td>mode</td>
<td>integer specifying access mode required: see ‘Details’.</td>
</tr>
</tbody>
</table>
file.choose

Choose a File Interactively

Description

Choose a file interactively.

Usage

file.choose(new = FALSE)

Arguments

new Logical: choose the style of dialog box presented to the user: at present only new = FALSE is used.
Value
A character vector of length one giving the file path.

See Also
list.files for non-interactive selection.

Description
Utility function to extract information about files on the user’s file systems.

Usage
file.info(..., extra_cols = TRUE)

file.mode(...)
file.mtime(...)
file.size(...)

Arguments
... character vectors containing file paths. Tilde-expansion is done: see path.expand.
extra_cols Logical: return all cols rather than just the first six.

Details
What constitutes a ‘file’ is OS-dependent but includes directories. (However, directory names must not include a trailing backslash or slash on Windows.) See also the section in the help for file.exists on case-insensitive file systems.

The file ‘mode’ follows POSIX conventions, giving three octal digits summarizing the permissions for the file owner, the owner’s group and for anyone respectively. Each digit is the logical or of read (4), write (2) and execute/search (1) permissions.

See files for how file paths with marked encodings are interpreted.

On most systems symbolic links are followed, so information is given about the file to which the link points rather than about the link.

Value
For file.info, data frame with row names the file names and columns

size double: File size in bytes.
isdir logical: Is the file a directory?
mode integer of class "octmode". The file permissions, printed in octal, for example 644.
mtime, ctime, atime

integer of class "POSIXct": file modification, ‘last status change’ and last access times.

uid

integer: the user ID of the file’s owner.

gid

integer: the group ID of the file’s group.

uname

character: uid interpreted as a user name.

grname

character: gid interpreted as a group name.

Unknown user and group names will be NA.

If extra_cols is false, only the first six columns are returned: as these can all be found from a single C system call this can be faster. (However, properly configured systems will use a ‘name service cache daemon’ to speed up the name lookups.)

Entries for non-existent or non-readable files will be NA. The uid, gid, uname and grname columns may not be supplied on a non-POSIX Unix-alike system, and will not be on Windows.

What is meant by the three file times depends on the OS and file system. On Windows native file systems ctime is the file creation time (something which is not recorded on most Unix-alike file systems). What is meant by ‘file access’ and hence the ‘last access time’ is system-dependent.

The times are reported to an accuracy of seconds, and perhaps more on some systems. However, many file systems only record times in seconds, and some (e.g., modification time on FAT systems) are recorded in increments of 2 or more seconds.

file.mode, file.mtime and file.size are convenience wrappers returning just one of the columns.

Note

Some systems allow files of more than 2Gb to be created but not accessed by the stat system call. Such files will show up as non-readable (and very likely not be readable by any of R’s input functions) – fortunately such file systems are becoming rare.

See Also

Sys.readlink to find out about symbolic links, files, file.access, list.files, and DateTimeClasses for the date formats.

Sys.chmod to change permissions.

Examples

col(finf <- file.info(dir())) # at least six
finf # the whole list

## Those that are more than 100 days old:
finf <- file.info(dir(), extra_cols = FALSE)
finf[difftime(Sys.time(), finf[,"mtime"], units = "days") > 100 , 1:4]

file.info("no-such-file-exists")
file.show  

Display One or More Text Files

Description

Display one or more (plain) text files, in a platform specific way, typically via a 'pager'.

Usage

file.show(..., header = rep('"", nfiles),
           title = "R Information",
           delete.file = FALSE, pager = getOption("pager"),
           encoding = "")
Arguments

... one or more character vectors containing the names of the files to be displayed. Paths with have tilde expansion.
header character vector (of the same length as the number of files specified in ...) giving a header for each file being displayed. Defaults to empty strings.
title an overall title for the display. If a single separate window is used for the display, title will be used as the window title. If multiple windows are used, their titles should combine the title and the file-specific header.
delete.file should the files be deleted after display? Used for temporary files.
pager the pager to be used: not used on all platforms encoding character string giving the encoding to be assumed for the file(s).

Details

This function provides the core of the R help system, but it can be used for other purposes as well, such as page.

How the pager is implemented is highly system-dependent.

The basic Unix version concatenates the files (using the headers) to a temporary file, and displays it in the pager selected by the pager argument, which is a character vector specifying a system command (a full path or a command found on the PATH) to run on the set of files. The ‘factory-fresh’ default is to use ‘R_HOME/bin/pager’, which is a shell script running the command-line specified by the environment variable PAGER whose default is set at configuration, usually to less. On a Unix-alike more is used if pager is empty.

Most GUI systems will use a separate pager window for each file, and let the user leave it up while R continues running. The selection of such pagers could either be done using special pager names being intercepted by lower-level code (such as "internal" and "console" on Windows), or by letting pager be an R function which will be called with arguments (files,header,title,delete.file) corresponding to the first four arguments of file.show and take care of interfacing to the GUI.

The R.app GUI on macOS uses its internal pager irrespective of the setting of pager.

Not all implementations will honour delete.file. In particular, using an external pager on Windows does not, as there is no way to know when the external application has finished with the file.

File Manipulation

Description

These functions provide a low-level interface to the computer’s file system.

Usage

file.create(..., showWarnings = TRUE)
file.exists(...)
file.remove(...)
file.rename(from, to)
file.append(file1, file2)
file.copy(from, to, overwrite = recursive, recursive = FALSE,
          copy.mode = TRUE, copy.date = FALSE)
file.symlink(from, to)
file.link(from, to)

Arguments

..., file1, file2
character vectors, containing file names or paths.
from, to
character vectors, containing file names or paths. For file.copy and
file.symlink to can alternatively be the path to a single existing directory.
overwrite
logical; should existing destination files be overwritten?
showWarnings
logical; should the warnings on failure be shown?
recursive
logical. If to is a directory, should directories in from be copied (and their
contents)? (Like cp -R on POSIX OSes.)
copy.mode
logical: should file permission bits be copied where possible?
copy.date
logical: should file dates be preserved where possible? See Sys.setFileTime.

Details

The ... arguments are concatenated to form one character string: you can specify the files sepa-
rately or as one vector. All of these functions expand path names: see path.expand.

file.create creates files with the given names if they do not already exist and truncates them if
they do. They are created with the maximal read/write permissions allowed by the ‘umask’ setting
(where relevant). By default a warning is given (with the reason) if the operation fails.

file.exists returns a logical vector indicating whether the files named by its argument exist.
(Here ‘exists’ is in the sense of the system’s stat call: a file will be reported as existing only if you
have the permissions needed by stat. Existence can also be checked by file.access, which might
use different permissions and so obtain a different result. Note that the existence of a file does not
imply that it is readable: for that use file.access.) What constitutes a ‘file’ is system-dependent,
but should include directories. (However, directory names must not include a trailing backslash or
slash on Windows.) Note that if the file is a symbolic link on a Unix-alike, the result indicates if
the link points to an actual file, not just if the link exists. Lastly, note the different function exists
which checks for existence of R objects.
file.remove attempts to remove the files named in its argument. On most Unix platforms ‘file’ includes empty directories, symbolic links, fifos and sockets. On Windows, ‘file’ means a regular file and not, say, an empty directory.

file.rename attempts to rename files (and from and to must be of the same length). Where file permissions allow this will overwrite an existing element of to. This is subject to the limitations of the OS’s corresponding system call (see something like man 2 rename on a Unix-alike): in particular in the interpretation of ‘file’: most platforms will not rename files from one file system to another. **NB:** This means that renaming a file from a temporary directory to the user’s filesystem or during package installation will often fail. (On Windows, file.rename can rename files but not directories across volumes.) On platforms which allow directories to be renamed, typically neither or both of from and to must a directory, and if to exists it must be an empty directory.

file.append attempts to append the files named by its second argument to those named by its first. The R subscript recycling rule is used to align names given in vectors of different lengths.

file.copy works in a similar way to file.append but with the arguments in the natural order for copying. Copying to existing destination files is skipped unless overwrite = TRUE. The to argument can specify a single existing directory. If copy.mode = TRUE file read/write/execute permissions are copied where possible, restricted by ‘umask’. (On Windows this applies only to files.) Other security attributes such as ACLs are not copied. On a POSIX filesystem the targets of symbolic links will be copied rather than the links themselves, and hard links are copied separately. Using copy.date = TRUE may or may not copy the timestamp exactly (for example, fractional seconds may be omitted), but is more likely to do so as from R 3.4.0.

file.symlink and file.link make symbolic and hard links on those file systems which support them. For file.symlink the to argument can specify a single existing directory. (Unix and macOS native filesystems support both. Windows has hard links to files on NTFS file systems and concepts related to symbolic links on recent versions: see the section below on the Windows version of this help page. What happens on a FAT or SMB-mounted file system is OS-specific.)

File arguments with a marked encoding (see Encoding are if possible translated to the native encoding, except on Windows where Unicode file operations are used (so marking as UTF-8 can be used to access file paths not in the native encoding on suitable file systems).

**Value**

These functions return a logical vector indicating which operation succeeded for each of the files attempted. Using a missing value for a file or path name will always be regarded as a failure.

If showWarnings = TRUE, file.create will give a warning for an unexpected failure.

**Case-insensitive file systems**

Case-insensitive file systems are the norm on Windows and macOS, but can be found on all OSes (for example a FAT-formatted USB drive is probably case-insensitive).

These functions will most likely match existing files regardless of case on such file systems: however this is an OS function and it is possible that file names might be mapped to upper or lower case.

**Warning**

Always check the return value of these functions when used in package code. This is especially important for file.rename, which has OS-specific restrictions (and note that the session temporary directory is commonly on a different file system from the working directory): it is only portable to use file.rename to change file name(s) within a single directory.

setwd("tmp")
file.remove("A") # the tmp/A file
file.symlink(file.path("..", c("A", "B")), ").")
    # |--> (TRUE, FALSE) : ok for A but not B as it exists already
setwd("..")
unlink("tmp", recursive = TRUE)
file.remove("A", "B", "C")
```

files2 Manipulation of Directories and File Permissions

Description
These functions provide a low-level interface to the computer’s file system.

Usage

```r
dir.exists(paths)
dir.create(path, showWarnings = TRUE, recursive = FALSE, mode = "0777")
Sys.chmod(paths, mode = "0777", use_umask = TRUE)
Sys.umask(mode = NA)
```
Arguments

- **path**: a character vector containing a single path name. Tilde expansion (see `path.expand`) is done.
- **paths**: character vectors containing file or directory paths. Tilde expansion (see `path.expand`) is done.
- **showWarnings**: logical; should the warnings on failure be shown?
- **recursive**: logical. Should elements of the path other than the last be created? If true, like the Unix command `mkdir -p`.
- **mode**: the mode to be used on Unix-alikes: it will be coerced by `as.octmode`. For `Sys.chmod` it is recycled along paths.
- **use_umask**: logical: should the mode be restricted by the `umask` setting?

Details

dir.create creates the last element of the path, unless `recursive = TRUE`. Trailing path separators are discarded. The mode will be modified by the umask setting in the same way as for the system function `mkdir`. What modes can be set is OS-dependent, and it is unsafe to assume that more than three octal digits will be used. For more details see your OS’s documentation on the system call `mkdir`, e.g. `man 2 mkdir` (and not that on the command-line utility of that name).

One of the idiosyncrasies of Windows is that directory creation may report success but create a directory with a different name, for example `dir.create("G.S.")` creates "G.S". This is undocumented, and what are the precise circumstances is unknown (and might depend on the version of Windows). Also avoid directory names with a trailing space.

`Sys.chmod` sets the file permissions of one or more files. It may not be supported on a system (when a warning is issued). See the comments for `dir.create` for how modes are interpreted. Changing mode on a symbolic link is unlikely to work (nor be necessary). For more details see your OS’s documentation on the system call `chmod`, e.g. `man 2 chmod` (and not that on the command-line utility of that name). Whether this changes the permission of a symbolic link or its target is OS-dependent (although to change the target is more common, and POSIX does not support modes for symbolic links: BSD-based Unixes do, though).

`Sys.umask` sets the `umask` and returns the previous value: as a special case `mode = NA` just returns the current value. It may not be supported (when a warning is issued and "0" is returned). For more details see your OS’s documentation on the system call `umask`, e.g. `man 2 umask`.

How modes are handled depends on the file system, even on Unix-alikes (although their documentation is often written assuming a POSIX file system). So treat documentation cautiously if you are using, say, a FAT/FAT32 or network-mounted file system.

See `files` for how file paths with marked encodings are interpreted.

Value

dir.exists returns a logical vector of `TRUE` or `FALSE` values (without names).

dir.create and `Sys.chmod` return invisibly a logical vector indicating if the operation succeeded for each of the files attempted. Using a missing value for a path name will always be regarded as a failure. `dir.create` indicates failure if the directory already exists. If `showWarnings = TRUE`, `dir.create` will give a warning for an unexpected failure (e.g., not for a missing value nor for an already existing component for `recursive = TRUE`).

`Sys.umask` returns the previous value of the `umask`, as a length-one object of class "octmode": the visibility flag is off unless mode is NA.

See also the section in the help for `file.exists` on case-insensitive file systems for the interpretation of path and paths.
find.package

Find Packages

Description

Find the paths to one or more packages.

Usage

find.package(package, lib.loc = NULL, quiet = FALSE, verbose = getOption("verbose"))

path.package(package, quiet = FALSE)

packageNotFoundError(package, lib.loc, call = NULL)

Arguments

package character vector: the names of packages.
lib.loc a character vector describing the location of R library trees to search through, or NULL. The default value of NULL corresponds to checking the loaded namespace, then all libraries currently known in .libPaths().
quiet logical. Should this not give warnings or an error if the package is not found?
verbose a logical. If TRUE, additional diagnostics are printed, notably when a package is found more than once.
call call expression.

Examples

## Not run:
## Fix up maximal allowed permissions in a file tree
Sys.chmod(list.dirs("."), "777")
f <- list.files("." , all.files = TRUE, full.names = TRUE, recursive = TRUE)
Sys.chmod(f, (file.info(f)$mode | "664"))

## End(Not run)
findInterval

Find Interval Numbers or Indices

Details

find.package returns path to the locations where the given packages are found. If lib.loc is NULL, then loaded namespaces are searched before the libraries. If a package is found more than once, the first match is used. Unless quiet = TRUE a warning will be given about the named packages which are not found, and an error if none are. If verbose is true, warnings about packages found more than once are given. For a package to be returned it must contain a either a ‘Meta’ subdirectory or a ‘DESCRIPTION’ file containing a valid version field, but it need not be installed (it could be a source package if lib.loc was set suitably).

find.package is not usually the right tool to find out if a package is available for use: the only way to do that is to use require to try to load it. It need not be installed for the correct platform, it might have a version requirement not met by the running version of R, there might be dependencies which are not available, ...

path.package returns the paths from which the named packages were loaded, or if none were named, for all currently attached packages. Unless quiet = TRUE it will warn if some of the packages named are not attached, and given an error if none are.

packageNotFoundError creates an error condition object of class packageNotFoundError for signaling errors. The condition object contains the fields package and lib.loc.

Value

A character vector of paths of package directories.

See Also

path.expand and normalizePath for path standardization.

Examples

try(find.package("knitr"))
## will not give an error, maybe a warning about *all* locations it is found:
find.package("kitty", quiet=TRUE, verbose=TRUE)

## Find all .libPaths() entries a package is found:
findPkgAll <- function(pkg)
  unlist(lapply(.libPaths(), function(lib)
    find.package(pkg, lib, quiet=TRUE, verbose=FALSE)))

findPkgAll("MASS")
findPkgAll("knitr")

findInterval

Find Interval Numbers or Indices

Description

Given a vector of non-decreasing breakpoints in vec, find the interval containing each element of x; i.e., if i <- findInterval(x, v), for each index j in x v[i] <= x[j] < v[i+1] where v[0] := -\infty, v[N+1] := +\infty, and N < length(v). At the two boundaries, the returned index may differ by 1, depending on the optional arguments rightmost.closed and all.inside.
findInterval

**Usage**

```r
findInterval(x, vec, rightmost.closed = FALSE, all.inside = FALSE,
left.open = FALSE)
```

**Arguments**

- `x` numeric.
- `vec` numeric, sorted (weakly) increasingly, of length `N`, say.
- `rightmost.closed` logical; if true, the rightmost interval, `vec[N-1] .. vec[N]` is treated as closed, see below.
- `all.inside` logical; if true, the returned indices are coerced into `1,...,N-1`, i.e., 0 is mapped to 1 and N to N-1.
- `left.open` logical; if true, all the intervals are open at left and closed at right; in the formulas below, `≤` should be swapped with `< (and > with `≥`), and `rightmost.closed` means 'leftmost is closed'. This may be useful, e.g., in survival analysis computations.

**Details**

The function `findInterval` finds the index of one vector `x` in another, `vec`, where the latter must be non-decreasing. Where this is trivial, equivalent to `apply( outer(x, vec, ">="), 1, sum)`, as a matter of fact, the internal algorithm uses interval search ensuring $O(n \log N)$ complexity where `n <- length(x)` and `N <- length(vec)`. For (almost) sorted `x`, it will be even faster, basically $O(n)$.

This is the same computation as for the empirical distribution function, and indeed, `findInterval(t, sort(X))` is identical to `nF_n(t; X_1,...,X_n)` where $F_n$ is the empirical distribution function of $X_1,...,X_n$.

When `rightmost.closed = TRUE`, the result for `x[j] = vec[N]` (`= max vec`) is `N - 1` as for all other values in the last interval.

`left.open = TRUE` is occasionally useful, e.g., for survival data. For (anti-)symmetry reasons, it is equivalent to using “mirrored” data, i.e., the following is always true:

```r
identical(
  findInterval( x, v, left.open= TRUE, ...) ,
  N - findInterval(-x, -v[1:N], left.open=FALSE, ...) )
```

where `N <- length(vec)` as above.

**Value**

vector of length `length(x)` with values in `0:N` (and NA) where `N <- length(vec)`, or values coerced to `1:(N-1)` if and only if `all.inside = TRUE` (equivalently coercing all `x` values inside the intervals). Note that `NA`s are propagated from `x`, and `Inf` values are allowed in both `x` and `vec`.

**Author(s)**

Martin Maechler
See Also

`approx(*,method = "constant")` which is a generalization of `findInterval()`. `ecdf` for computing the empirical distribution function which is (up to a factor of \( n \)) also basically the same as `findInterval(.)`.

Examples

```r
x <- 2:18
v <- c(5, 10, 15)  # create two bins [5,10) and [10,15)
cbind(x, findInterval(x, v))

N <- 100
X <- sort(round(stats::rt(N, df = 2), 2))
tt <- c(-100, seq(-2, 2, len = 201), +100)
it <- findInterval(tt, X)
if [it < 1 | it >= N] # only first and last are outside range(X)
## 'left.open = TRUE' means "mirroring" :
N <- length(v)
stopifnot(identical(
  findInterval( x, v, left.open=TRUE) ,
  N - findInterval(-x, -v[N:1])))
```

---

**force**

---

**Force Evaluation of an Argument**

**Description**

Forces the evaluation of a function argument.

**Usage**

`force(x)`

**Arguments**

- `x`: a formal argument of the enclosing function.

**Details**

`force` forces the evaluation of a formal argument. This can be useful if the argument will be captured in a closure by the lexical scoping rules and will later be altered by an explicit assignment or an implicit assignment in a loop or an apply function.

**Note**

This is semantic sugar: just evaluating the symbol will do the same thing (see the examples).

`force` does not force the evaluation of other promises. (It works by forcing the promise that is created when the actual arguments of a call are matched to the formal arguments of a closure, the mechanism which implements lazy evaluation.)
Examples

```r
f <- function(y) function() y
lf <- vector("list", 5)
for (i in seq_along(lf)) lf[[i]] <- f(i)
lf[[1]]() # returns 5

g <- function(y) { force(y); function() y }
lg <- vector("list", 5)
for (i in seq_along(lg)) lg[[i]] <- g(i)
lg[[1]]() # returns 1

## This is identical to
g <- function(y) { y; function() y }
```

---

**forceAndCall**  
*Call a function with Some Arguments Forced*

Description

Call a function with a specified number of leading arguments forced before the call if the function is a closure.

Usage

```r
forceAndCall(n, FUN, ...)
```

Arguments

- `n` number of leading arguments to force.
- `FUN` function to call.
- `...` arguments to `FUN`.

Details

forceAndCall calls the function `FUN` with arguments specified in `...`. If the value of `FUN` is a closure then the first `n` arguments to the function are evaluated (i.e. their delayed evaluation promises are forced) before executing the function body. If the value of `FUN` is a primitive then the call `FUN(...)` is evaluated in the usual way.

forceAndCall is intended to help defining higher order functions like `apply` to behave more reasonably when the result returned by the function applied is a closure that captured its arguments.

See Also

`force`, `promise`, `closure`. 
Foreign Function Interface

Description

Functions to make calls to compiled code that has been loaded into R.

Usage

\texttt{.C(.NAME, ..., NAOK = FALSE, DUP = TRUE, PACKAGE, ENCODING)}
\texttt{.Fortran(.NAME, ..., NAOK = FALSE, DUP = TRUE, PACKAGE, ENCODING)}

Arguments

\texttt{.NAME} a character string giving the name of a C function or Fortran subroutine, or an object of class "NativeSymbolInfo", "RegisteredNativeSymbol" or "NativeSymbol" referring to such a name.

\texttt{...} arguments to be passed to the foreign function. Up to 65.

\texttt{NAOK} if TRUE then any \texttt{NA} or \texttt{NaN} or \texttt{Inf} values in the arguments are passed on to the foreign function. If FALSE, the presence of \texttt{NA} or \texttt{NaN} or \texttt{Inf} values is regarded as an error.

\texttt{PACKAGE} if supplied, confine the search for a character string .NAME to the DLL given by this argument (plus the conventional extension, ".so", ".dll", ...). This is intended to add safety for packages, which can ensure by using this argument that no other package can override their external symbols, and also speeds up the search (see 'Note').

\texttt{DUP, ENCODING} For back-compatibility, accepted but ignored.

Details

These functions can be used to make calls to compiled C and Fortran 77 code. Later interfaces are \texttt{.Call} and \texttt{.External} which are more flexible and have better performance.

These functions are \texttt{primitive}, and .NAME is always matched to the first argument supplied (which should not be named). The other named arguments follow \texttt{...} and so cannot be abbreviated. For clarity, should avoid using names in the arguments passed to \texttt{...} that match or partially match .NAME.

Value

A list similar to the \texttt{...} list of arguments passed in (including any names given to the arguments), but reflecting any changes made by the C or Fortran code.

Argument types

The mapping of the types of R arguments to C or Fortran arguments is

<table>
<thead>
<tr>
<th>R</th>
<th>C</th>
<th>Fortran</th>
</tr>
</thead>
<tbody>
<tr>
<td>integer</td>
<td>int *</td>
<td>integer</td>
</tr>
<tr>
<td>numeric</td>
<td>double *</td>
<td>double precision</td>
</tr>
<tr>
<td>– or –</td>
<td>float *</td>
<td>real</td>
</tr>
</tbody>
</table>
complex Rcomplex * double complex
logical int * integer
character char ** [see below]
raw unsigned char * not allowed
list SEXP * not allowed
other SEXP not allowed

Note: The C types corresponding to integer and logical are int, not long as in S. This difference matters on most 64-bit platforms, where int is 32-bit and long is 64-bit (but not on 64-bit Windows).

Note: The Fortran type corresponding to logical is integer, not logical: the difference matters on some Fortran compilers.

Numeric vectors in R will be passed as type double * to C (and as double precision to Fortran) unless the argument has attribute Csingle set to TRUE (use as.single or single). This mechanism is only intended to be used to facilitate the interfacing of existing C and Fortran code.

The C type Rcomplex is defined in ‘Complex.h’ as a typedef struct {double r; double i;}. It may or may not be equivalent to the C99 double complex type, depending on the compiler used.

Logical values are sent as 0 (FALSE), 1 (TRUE) or INT_MIN = -2147483648 (NA, but only if NAOK = TRUE), and the compiled code should return one of these three values: however non-zero values other than INT_MIN are mapped to TRUE.

Missing (NA) string values are passed to .C as the string "NA". As the C char type can represent all possible bit patterns there appears to be no way to distinguish missing strings from the string "NA". If this distinction is important use .Call.

Using a character string with .Fortran is deprecated and will give a warning. It passes the first (only) character string of a character vector as a C character array to Fortran: that may be usable as character*255 if its true length is passed separately. Only up to 255 characters of the string are passed back. (How well this works, and even if it works at all, depends on the C and Fortran compilers and the platform.)

Lists, functions or other R objects can (for historical reasons) be passed to .C, but the .Call interface is much preferred. All inputs apart from atomic vectors should be regarded as read-only, and all apart from vectors (including lists), functions and environments are now deprecated.

Fortran symbol names

All Fortran compilers known to be usable to compile R map symbol names to lower case, and so does .Fortran.

Symbol names containing underscores are not valid Fortran 77 (although they are valid in Fortran 9x). Many Fortran 77 compilers will allow them but may translate them in a different way to names not containing underscores. Such names will often work with .Fortran (since how they are translated is detected when R is built and the information used by .Fortran), but portable code should not use Fortran names containing underscores.

Use .Fortran with care for compiled Fortran 9x code: it may not work if the Fortran 9x compiler used differs from the Fortran 77 compiler used when configuring R, especially if the subroutine name is not lower-case or includes an underscore. It is possible to use .C and do any necessary symbol-name translation yourself.
**Copying of arguments**

Character vectors are copied before calling the compiled code and to collect the results. For other atomic vectors the argument is copied before calling the compiled code if it is otherwise used in the calling code.

Non-atomic-vector objects are read-only to the C code and are never copied.

This behaviour can be changed by setting `options(CBoundsCheck = TRUE)`. In that case raw, logical, integer, double and complex vector arguments are copied both before and after calling the compiled code. The first copy made is extended at each end by guard bytes, and on return it is checked that these are unaltered. For `.C`, each element of a character vector uses guard bytes.

**Note**

If one of these functions is to be used frequently, do specify `PACKAGE` (to confine the search to a single DLL) or pass `.NAME` as one of the native symbol objects. Searching for symbols can take a long time, especially when many namespaces are loaded.

You may see `PACKAGE = "base"` for symbols linked into R. Do not use this in your own code: such symbols are not part of the API and may be changed without warning.

---

**formals**  
*Access to and Manipulation of the Formal Arguments*

**Description**

Get or set the formal arguments of a `function`.

**Usage**

```r
formals(fun = sys.function(sys.parent()), envir = parent.frame())
formals(fun, envir = environment(fun)) <- value
```

**Arguments**

- `fun`  
a `function`, or see ‘Details’.
- `envir`  
`environment` in which the function should be defined (or found via `get()` in the first case and when `fun` a character string).
- `value`  
a list (or pairlist) of R expressions.
Details

For the first form, fun can also be a character string naming the function to be manipulated, which
is searched for in envir, by default from the parent frame. If it is not specified, the function calling
formals is used.

Only closures have formals, not primitive functions.

Value

formals returns the formal argument list of the function specified, as a pairlist, or NULL for a
non-function or primitive.

The replacement form sets the formals of a function to the list/pairlist on the right hand side, and
(potentially) resets the environment of the function, dropping attributes.

See Also

formalArgs (from methods), a shortcut for names(formals(.)). args for a human-readable ver-
sion, alist to construct a typical formals value, see the examples.

The three parts of a (non-primitive) function are its formals, body, and environment.

Examples

require(stats)
formals(lm)

## If you just want the names of the arguments, use formalArgs instead.
names(formals(lm))
methods::: formalArgs(lm)  # same

## formals returns a pairlist. Arguments with no default have type symbol (aka name).
str(formals(lm))

## formals returns NULL for primitive functions. Use it in combination with
## args for this case.
is.primitive('+')
formals('+')
formals(args('+'))

## You can overwrite the formal arguments of a function (though this is
## advanced, dangerous coding).
f <- function(x) a + b
formals(f) <- alist(a = , b = 3)
f  # function(a, b = 3) a + b
f(2) # result = 5

format Encode in a Common Format

Description

Format an R object for pretty printing.
Usage

format(x, ...)

## Default S3 method:
format(x, trim = FALSE, digits = NULL, nsmall = 0L,  
   justify = c("left", "right", "centre", "none"), 
   width = NULL, na.encode = TRUE, scientific = NA,  
   big.mark = "", big.interval = 3L, 
   small.mark = "", small.interval = 5L, 
   decimal.mark = getOption("OutDec"), 
   zero.print = NULL, drop0trailing = FALSE, ...)

## S3 method for class 'data.frame'
format(x, ..., justify = "none")

## S3 method for class 'factor'
format(x, ...)

## S3 method for class 'AsIs'
format(x, width = 12, ...)

Arguments

x any R object (conceptually); typically numeric.
trim logical; if FALSE, logical, numeric and complex values are right-justified to a common width: if TRUE the leading blanks for justification are suppressed.
digits how many significant digits are to be used for numeric and complex x. The default, NULL, uses getOption("digits"). This is a suggestion: enough decimal places will be used so that the smallest (in magnitude) number has this many significant digits, and also to satisfy nsmall. (For the interpretation for complex numbers see signif.)
nsmall the minimum number of digits to the right of the decimal point in formatting real/complex numbers in non-scientific formats. Allowed values are 0 <= nsmall <= 20.
justify should a character vector be left-justified (the default), right-justified, centred or left alone. Can be abbreviated.
width default method: the minimum field width or NULL or 0 for no restriction. 
   AsIs method: the maximum field width for non-character objects. NULL corresponds to the default 12.
na.encode logical: should NA strings be encoded? Note this only applies to elements of character vectors, not to numerical, complex nor logical NAs, which are always encoded as "NA".
scientific Either a logical specifying whether elements of a real or complex vector should be encoded in scientific format, or an integer penalty (see options("scipen")). Missing values correspond to the current default penalty.
...
   further arguments passed to or from other methods.
big.mark, big.interval, small.mark, small.interval, decimal.mark, zero.print, drop0trailing
   used for prettying (longish) numerical and complex sequences. Passed to prettyNum: that help page explains the details.
format is a generic function. Apart from the methods described here there are methods for dates (see `format.Date`), date-times (see `format.POSIXct`) and for other classes such as `format.octmode` and `format.dist`.

`format.data.frame` formats the data frame column by column, applying the appropriate method of `format` for each column. Methods for columns are often similar to `as.character` but offer more control. Matrix and data-frame columns will be converted to separate columns in the result, and character columns (normally all) will be given class "AsIs".

`format.factor` converts the factor to a character vector and then calls the default method (and so justify applies).

`format.AsIs` deals with columns of complicated objects that have been extracted from a data frame. Character objects and (atomic) matrices are passed to the default method (and so width does not apply). Otherwise it calls `toString` to convert the object to character (if a vector or list, element by element) and then right-justifies the result.

Justification for character vectors (and objects converted to character vectors by their methods) is done on display width (see `nchar`), taking double-width characters and the rendering of special characters (as escape sequences, including escaping backslash but not double quote: see `print.default`) into account. Thus the width is as displayed by `print(quote = FALSE)` and not as displayed by `cat`. Character strings are padded with blanks to the display width of the widest. (If `na.encode = FALSE` missing character strings are not included in the width computations and are not encoded.)

Numeric vectors are encoded with the minimum number of decimal places needed to display all the elements to at least the digits significant digits. However, if all the elements then have trailing zeroes, the number of decimal places is reduced until `nsmall` is reached or at least one element has a non-zero final digit; see also the argument documentation for `big.*`, `small.*` etc, above. See the note in `print.default` about digits >= 16.

Raw vectors are converted to their 2-digit hexadecimal representation by `as.character`.

`format.default(x)` now provides a “minimal” string when `isS4(x)` is true.

The internal code respects the option `getOption("OutDec")` for the ‘decimal mark’, so if this is set to something other than "." then it takes precedence over argument `decimal.mark`.

Value

An object of similar structure to `x` containing character representations of the elements of the first argument `x` in a common format, and in the current locale’s encoding.

For character, numeric, complex or factor `x`, `dms` and `dimnames` are preserved on matrices/arrays and names on vectors: no other attributes are copied.

If `x` is a list, the result is a character vector obtained by applying `format.default(x,...)` to each element of the list (after `unlisting` elements which are themselves lists), and then collapsing the result for each element with `paste(collapse = ",")`. The defaults in this case are `trim = TRUE`, `justify = "none"` since one does not usually want alignment in the collapsed strings.

cc <- methods::getClassDef("standardGeneric")
format(cc) # "<S4 class ......>"

---

format.info format(.) Information

Description

Information is returned on how format(x,digits,nsmall) would be formatted.

Usage

format.info(x, digits = NULL, nsmall = 0)

Arguments

x an atomic vector; a potential argument of format(x,...).
digits how many significant digits are to be used for numeric and complex x. The
default, NULL, usesgetOption("digits").
nsmall (see format(...,nsmall)).
Value

An integer vector of length 1, 3 or 6, say \( r \).

For logical, integer and character vectors a single element, the width which would be used by `format` if `width = NULL`.

For numeric vectors:

- \( r[1] \): width (in characters) used by `format(x)`
- \( r[2] \): number of digits after decimal point.
- \( r[3] \): in \( 0:2 \); if \( \geq 1 \), exponential representation would be used, with exponent length of \( r[3]+1 \).

For a complex vector the first three elements refer to the real parts, and there are three further elements corresponding to the imaginary parts.

See Also

- `format` (notably about `digits >= 16`), `formatC`.

Examples

```r
dd <- options("digits") ; options(digits = 7) #-- for the following
format.info(123)  # 3 0 0
format.info(pi)   # 8 6 0
format.info(1e8)  # 5 0 1 - exponential "1e+08"
format.info(1e222) # 6 0 2 - exponential "1e+222"

x <- pi*10^c(-10,-2,0:2,8,20)
names(x) <- formatC(x, width = 1, digits = 3, format = "g")
cbind(sapply(x, format))
t(sapply(x, format.info))

## using at least 8 digits right of "."
t(sapply(x, format.info, nsmall = 8))

# Reset old options:
options(dd)
```

format.pval | Format P Values

Description

`format.pval` is intended for formatting p-values.

Usage

```r
format.pval(pv, digits = max(1,getOption("digits") - 2),
            eps = .Machine$double.eps, na.form = "NA", ...)
```
formatC

Arguments

- \texttt{pv} a numeric vector.
- \texttt{digits} how many significant digits are to be used.
- \texttt{eps} a numerical tolerance: see ‘Details’.
- \texttt{na.form} character representation of \texttt{NA}s.
- \texttt{...} further arguments to be passed to \texttt{format} such as \texttt{nsmall}.

Details

\texttt{format.pval} is mainly an auxiliary function for \texttt{print.summary.lm} etc., and does separate formatting for fixed, floating point and very small values; those less than \texttt{eps} are formatted as “\textless [eps]” (where \texttt{[eps]} stands for \texttt{format(eps,digits)}).

Value

A character vector.

Examples

\begin{verbatim}
format.pval(c(stats::runif(5), pi^-100, NA))
format.pval(c(0.1, 0.0001, 1e-27))
\end{verbatim}

\begin{table}[h]
\centering
\begin{tabular}{|c|c|}
\hline
\textbf{formatC} & \textbf{Formatting Using C-style Formats} \\
\hline
\end{tabular}
\end{table}

Description

\texttt{formatC()} formats numbers individually and flexibly using \texttt{C} style format specifications.

\texttt{prettyNum()} is used for “prettifying” (possibly formatted) numbers, also in \texttt{format.default}.

\texttt{.format.zeros(x)}, an auxiliary function of \texttt{prettyNum()}, re-formats the zeros in a vector \texttt{x} of formatted numbers.

Usage

\begin{verbatim}
formatC(x, digits = NULL, width = NULL,
format = NULL, flag = "", mode = NULL,
big.mark = "", big.interval = 3L,
small.mark = "", small.interval = 5L,
decimal.mark = getOption("OutDec"),
preserve.width = "individual",
zero.print = NULL, replace.zero = TRUE,
drop0trailing = FALSE)

prettyNum(x, big.mark = "", big.interval = 3L,
small.mark = "", small.interval = 5L,
decimal.mark = getOption("OutDec"), input.d.mark = decimal.mark,
preserve.width = c("common", "individual", "none"),
zero.print = NULL, replace.zero = FALSE,
drop0trailing = FALSE, is.complex = NA,
\end{verbatim}
\dots

\texttt{\textbf{formatC}}

\texttt{.format.zeros(x, zero.print, nx = suppressWarnings(as.numeric(x)),
replace = FALSE, warn.non.fitting = TRUE)}

\textbf{Arguments}

\begin{itemize}
\item \textbf{x} \hspace{1cm} an atomic numerical or character object, possibly \texttt{complex} only for \texttt{prettyNum()}, typically a vector of real numbers. Any class is discarded, with a warning.
\item \textbf{digits} \hspace{1cm} the desired number of digits after the decimal point (\texttt{format = "f"}) or \texttt{significant} digits (\texttt{format = "g", = "e" or = "fg"}). Default: 2 for integer, 4 for real numbers. If less than 0, the C default of 6 digits is used. If specified as more than 50, 50 will be used with a warning unless \texttt{format = "f"} where it is limited to typically 324. (Not more than 15–21 digits need be accurate, depending on the OS and compiler used. This limit is just a precaution against segfaults in the underlying C runtime.)
\item \textbf{width} \hspace{1cm} the total field width; if both \texttt{digits} and \texttt{width} are unspecified, \texttt{width} defaults to 1, otherwise to \texttt{digits + 1}. \texttt{width = 0} will use \texttt{width = digits, width < 0} means left justify the number in this field (equivalent to \texttt{flag = "-"}). If necessary, the result will have more characters than width. For character data this is interpreted in characters (not bytes nor display width).
\item \textbf{format} \hspace{1cm} equal to \texttt{"d" (for integers)}, \texttt{"f"}, \texttt{"e"}, \texttt{"E"}, \texttt{"g"}, \texttt{"G"}, \texttt{"fg"} (for reals), or \texttt{"s" (for strings)}. Default is \texttt{"d" for integers, "g" for reals.} \texttt{"f" gives numbers in the usual xxx.xxx format; "e" and "E" give n.ddde+nn or n.dddE+nn (scientific format); "g" and "G" put x[i] into scientific format only if it saves space to do so and drop trailing zeros and decimal point - unless \texttt{flag} contains "#" which keeps trailing zeros for the "g", "G" formats.} \texttt{"fg" (our own hybrid format) uses fixed format as "f", but digits as the minimum number of \texttt{significant} digits. This can lead to quite long result strings, see examples below. Note that unlike \texttt{signif} this prints large numbers with more significant digits than \texttt{digits}. Trailing zeros are \texttt{dropped} in this format, unless \texttt{flag} contains "#".}
\item \textbf{flag} \hspace{1cm} for \texttt{formatC}, a character string giving a format modifier as in Kernighan and Ritchie (1988, page 243) or the C++99 standard. \texttt{"0" pads leading zeros; \texttt{"-" does left adjustment, \texttt{"+" ensures a sign in all cases, i.e., +" for positive numbers, \texttt{"" if the first character is not a sign, the space character " " will be used instead. \texttt{"#" specifies "an alternative output form", specifically depending on \texttt{format}, \texttt{"" on some platform--locale combination, activates "thousands’ grouping" for decimal conversion, \texttt{"I" in some versions of ‘glibc’ allow for integer conversion to use the locale’s alternative output digits, if any.}}}
\end{itemize}

There can be more than one of these flags, in any order. Other characters used to have no effect for character formatting, but signal an error since R 3.4.0.

\begin{itemize}
\item \textbf{mode} \hspace{1cm} \texttt{"double" (or "real"), "integer" or "character". Default: Determined from the storage mode of x.}}
\end{itemize}
big.mark character; if not empty used as mark between every big.interval decimals before (hence big) the decimal point.
big.interval see big.mark above; defaults to 3.
small.mark character; if not empty used as mark between every small.interval decimals after (hence small) the decimal point.
small.interval see small.mark above; defaults to 5.
decimal.mark the character to be used to indicate the numeric decimal point.
input.d.mark if x is character, the character known to have been used as the numeric decimal point in x.
preserve.width string specifying if the string widths should be preserved where possible in those cases where marks (big.mark or small.mark) are added. "common", the default, corresponds to format-like behavior whereas "individual" is the default in formatC(). Value can be abbreviated.
zero.print logical, character string or NULL specifying if and how zeros should be formatted specially. Useful for pretty printing 'sparse' objects.
replace.zero, replace logical; if zero.print is a character string, indicates if the exact zero entries in x should be simply replaced by zero.print. Otherwise, depending on the widths of the respective strings, the (formatted) zeroes are partly replaced by zero.print and then padded with " " to the right were applicable. In that case (false replace[.zero]), if the zero.print string does not fit, a warning is produced (if warn.non.fitting is true). This works via prettyNum(), which calls .format.zeros(*,replace=replace.zero) three times in this case, see the 'Details'.
warn.non.fitting logical; if it is true, replace[.zero] is false and the zero.print string does not fit, a warning is signalled.
drop0trailing logical, indicating if trailing zeros, i.e., "0" after the decimal mark, should be removed; also drops "e+00" in exponential formats. This is simply passed to prettyNum(), see the 'Details'.
is.complx optional logical, to be used when x is "character" to indicate if it stems from complex vector or not. By default (NA), x is checked to 'look like' complex.
... arguments passed to format.
x numeric vector of the same length as x, typically the numbers of which the character vector x is the pre-format.

details
For numbers, formatC() calls prettyNum() when needed which itself calls .format.zeros(*,replace=replace.zero). ("when needed": when zero.print is not NULL, drop0trailing is true, or one of big.mark, small.mark, or decimal.mark is not at default.)
If you set format it overrides the setting of mode, so formatC(123.45,mode = "double", format = "d") gives 123.
The rendering of scientific format is platform-dependent: some systems use n.ddde+nnn or n.dddenn rather than n.ddde+nn.

formatC does not necessarily align the numbers on the decimal point, so `formatC(c(6.11,13.1),digits = 2,format = "fg")` gives `c("6.1","13")`. If you want common formatting for several numbers, use `format`.

`prettyNum` is the utility function for prettifying `x`. `x` can be complex (or `format(<complex>)`), here. If `x` is not a character, `format(x[i],...)` is applied to each element, and then it is left unchanged if all the other arguments are at their defaults. Use the `input.d.mark` argument for `prettyNum(x)` when `x` is a character vector not resulting from something like `format(<number>)` with a period as decimal mark.

Because `gsub` is used to insert the `big.mark` and `small.mark`, special characters need escaping. In particular, to insert a single backslash, use "\\".

The C doubles used for R numerical vectors have signed zeros, which `formatC` may output as `-0, -0.000 ...`. There is a warning if `big.mark` and `decimal.mark` are the same: that would be confusing to those reading the output.

**Value**

A character object of same size and attributes as `x` (after discarding any class), in the current locale’s encoding.

Unlike `format`, each number is formatted individually. Looping over each element of `x`, the C function `sprintf(...)` is called for numeric inputs (inside the C function `str_signif`).

`formatC`: for character `x`, do simple (left or right) padding with white space.

**Note**

The default for `decimal.mark` in `formatC()` was changed in R 3.2.0: for use within `print` methods in packages which might be used with earlier versions: use `decimal.mark = getOption("OutDec")` explicitly.

**Author(s)**

`formatC` was originally written by Bill Dunlap for S-PLUS, later much improved by Martin Maechler.

It was first adapted for R by Friedrich Leisch and since much improved by the R Core team.

**References**

**See Also**

`format`

`sprintf` for more general C-like formatting.

**Examples**

```r
xx <- pi * 10^(-5:4)
cbind(format(xx, digits = 4), formatC(xx))
cbind(format(xx, width = 9, flag = "-"))
cbind(formatC(xx, digits = 5, width = 8, format = "f", flag = "0"))
cbind(format(xx, digits = 4), formatC(xx, digits = 4, format = "fg"))
```
f <- (-2:4); f <- f*16^f
# Default ("g") format:
formatC(pi*f)
# Fixed ("f") format, more than one flag ('width' partly "enlarged"):
cbind(formatC(pi*f, digits = 3, width=9, format = "f", flag = "0+"))

formatC(c("a", "Abc", "no way"), width = -7) # <=f flag = "-"
f <- (-2:4); f <- f*16^f
formatC(c(-1:1)/0, c(1,100)*pi), width = 8, digits = 1)

## note that some of the results here depend on the implementation
## of long-double arithmetic, which is platform-specific.
xx <- c(1e12,-3.98765e-10,1.45645e-69,1e-70,pi*1e37,3.44e4)

formatC(xx)
formatC(xx, format = "fg") # special "fixed" format.
formatC(xx[1:4], format = "f", digits = 75) # even longer strings

formatC(c(3.24, 2.3e-6), format = "f", digits = 11)
formatC(c(3.24, 2.3e-6), format = "f", digits = 11, drop0trailing = TRUE)

r <- c("76491283764.97430", "29.12345678901", "-7.1234", "-100.1","1123")

## American:
prettyNum(r, big.mark = ",")
## Some Europeans:
prettyNum(r, big.mark = "", decimal.mark = ",")

(dd <- sapply(1:10, function(i) paste((9:0)[1:i], collapse = ""))
prettyNum(dd, big.mark = "]")

## examples of 'small.mark'
pn <- stats::pnorm(1:7, lower.tail = FALSE)
cbind(format (pn, small.mark = " ", digits = 15))
cbind(formatC(pn, small.mark = " ", digits = 17, format = "f"))

ccf <- formatC(1.234 + 10^(0:8), format = "fg", width = 11, big.mark = "]")

## all with same width (one more than the specified minimum)
ccbind(ccf)

## Powers of two, stored exactly, formatted individually:
pow.2 <- formatC(2^-(1:32), digits = 24, width = 1, format = "fg")

## nicely printed (the last line showing 5^32 exactly):
noquote(cbind(pow.2))

## complex numbers:
r <- 10.0000001; rv <- (r/10)^(1:10)
(zv <- (rv + 1i*rv))
op <- options(digits = 7) ## (system default)
(pnv <- prettyNum(zv))
stopifnot(pnv == "1+1i", pnv == format(zv),
        pnv == prettyNum(zv, drop0trailing = TRUE))

## more digits change the picture:
options(digits = 8)
head(fv <- format(zv), 3)
prettyNum(fv)
prettyNum(fv, drop0trailing = TRUE) # a bit nicer
options(op)

## The ' flag :
doLC <- FALSE # <= R warns, so change to TRUE manually if you want see the effect
if(doLC) {
  oldLC <- Sys.getlocale("LC_NUMERIC")
  Sys.setlocale("LC_NUMERIC", "de_CH.UTF-8")
} formatC(1.234 + 10^(0:4), format = "fg", width = 11, flag = "")

## --> ..... " 1'001" " 10'001" on supported platforms
if(doLC) ## revert, typically to "C" :
  Sys.setlocale("LC_NUMERIC", oldLC)

---

Format Description Lists

Description

Format vectors of items and their descriptions as 2-column tables or LaTeX-style description lists.

Usage

formatDL(x, y, style = c("table", "list"),
         width = 0.9 * getOption("width"), indent = NULL)

Arguments

x a vector giving the items to be described, or a list of length 2 or a matrix with 2 columns giving both items and descriptions.
y a vector of the same length as x with the corresponding descriptions. Only used if x does not already give the descriptions.
style a character string specifying the rendering style of the description information.
width a positive integer giving the target column for wrapping lines in the output.
indent a positive integer specifying the indentation of the second column in table style, and the indentation of continuation lines in list style. Must not be greater than width/2, and defaults to width/3 for table style and width/9 for list style.

Details

After extracting the vectors of items and corresponding descriptions from the arguments, both are coerced to character vectors.

In table style, items with more than indent -3 characters are displayed on a line of their own.

Value

a character vector with the formatted entries.
Examples

```r
## Provide a nice summary of the numerical characteristics of the
## machine R is running on:
writeLines(formatDL(unlist(.Machine)))
## Inspect Sys.getenv() results in "list" style (by default, these are
## printed in "table" style):
writeLines(formatDL(Sys.getenv(), style = "list"))
```

---

**Function Definition**

**Description**

These functions provide the base mechanisms for defining new functions in the **R** language.

**Usage**

```r
function( arglist ) expr
\( arglist \) expr
return(value)
```

**Arguments**

- `arglist`: Empty or one or more name or name=expression terms.
- `expr`: An expression.
- `value`: An expression.

**Details**

The names in an argument list can be back-quoted non-standard names (see ‘backquote’).

If `value` is missing, NULL is returned. If it is a single expression, the value of the evaluated expression is returned. (The expression is evaluated as soon as `return` is called, in the evaluation frame of the function and before any on.exit expression is evaluated.)

If the end of a function is reached without calling `return`, the value of the last evaluated expression is returned.

The shorthand form \(x\) \(x + 1\) is parsed as `function(x) x + 1`. It may be helpful in making code containing simple function expressions more readable.

**Technical details**

This type of function is not the only type in **R**; they are called closures (a name with origins in **LISP**) to distinguish them from primitive functions.

A closure has three components, its `formals` (its argument list), its `body` (`expr` in the ‘Usage’ section) and its `environment` which provides the enclosure of the evaluation frame when the closure is used.

There is an optional further component if the closure has been byte-compiled. This is not normally user-visible, but is indicated when functions are printed.
The shorthand function notation is experimental and may change prior to release.

References

See Also

`args`, `formals`, `body` and `environment` for accessing the component parts of a function. `debug` for debugging; using `invisible` inside `return(.)` for returning `invisibly`.

Examples

```r
norm <- function(x) sqrt(x%*%x)
norm(1:4)
## An anonymous function:
(function(x, y){ z <- x^2 + y^2; x+y+z })(0:7, 1)
```

Description

Reduce uses a binary function to successively combine the elements of a given vector and a possibly given initial value. Filter extracts the elements of a vector for which a predicate (logical) function gives true. Find and Position give the first or last such element and its position in the vector, respectively. Map applies a function to the corresponding elements of given vectors. Negate creates the negation of a given function.

Usage

```r
Reduce(f, x, init, right = FALSE, accumulate = FALSE)
Filter(f, x)
Find(f, x, right = FALSE, nomatch = NULL)
Map(f, ...)
Negate(f)
Position(f, x, right = FALSE, nomatch = NA_integer_)
```

Arguments

- `f`: a function of the appropriate arity (binary for `Reduce`, unary for `Filter`, `Find` and `Position`, `k`-ary for `Map` if this is called with `k` arguments). An arbitrary predicate function for `Negate`.
- `x`: a vector.
- `init`: an R object of the same kind as the elements of `x`. 
right

accumulate

nomatch

... vectors.

Details

If init is given, Reduce logically adds it to the start (when proceeding left to right) or the end of x, respectively. If this possibly augmented vector v has n > 1 elements, Reduce successively applies f to the elements of v from left to right or right to left, respectively. I.e., a left reduce computes \( l_1 = f(v_1, v_2),\) \( l_2 = f(l_1, v_3),\) etc., and returns \( l_{n-1} = f(l_{n-2}, v_n),\) and a right reduce does \( r_{n-1} = f(v_{n-1}, v_n),\) \( r_{n-2} = f(v_{n-2}, r_{n-1})\) and returns \( r_1 = f(v_1, r_2).\) (E.g., if v is the sequence (2, 3, 4) and f is division, left and right reduce give \((2/3)/4 = 1/6\) and \(2/(3/4) = 8/3,\) respectively.) If v has only a single element, this is returned; if there are no elements, NULL is returned. Thus, it is ensured that f is always called with 2 arguments.

The current implementation is non-recursive to ensure stability and scalability.

Reduce is patterned after Common Lisp’s reduce. A reduce is also known as a fold (e.g., in Haskell) or an accumulate (e.g., in the C++ Standard Template Library). The accumulative version corresponds to Haskell’s scan functions.

Filter applies the unary predicate function f to each element of x, coercing to logical if necessary, and returns the subset of x for which this gives true. Note that possible NA values are currently always taken as false; control over NA handling may be added in the future. Filter corresponds to filter in Haskell or remove-if-not in Common Lisp.

Find and Position are patterned after Common Lisp’s find-if and position-if, respectively. If there is an element for which the predicate function gives true, then the first or last such element or its position is returned depending on whether right is false (default) or true, respectively. If there is no such element, the value specified by nomatch is returned. The current implementation is not optimized for performance.

Map is a simple wrapper to mapply which does not attempt to simplify the result, similar to Common Lisp’s mapcar (with arguments being recycled, however). Future versions may allow some control of the result type.

Negate corresponds to Common Lisp’s complement. Given a (predicate) function f, it creates a function which returns the logical negation of what f returns.

See Also

Function clusterMap and mcmapply (not Windows) in package parallel provide parallel versions of Map.

Examples

```r
## A general-purpose adder:
add <- function(x) Reduce("+", x)
add(list(1L, 2L, 3L))
```

## Like sum(), but can also used for adding matrices etc., as it will
## use the appropriate ‘+’ method in each reduction step.
## More generally, many generics meant to work on arbitrarily many
## arguments can be defined via reduction:
FOO <- function(...) Reduce(FOO2, list(...))
FOO2 <- function(x, y) UseMethod("FOO2")
## FOO() methods can then be provided via FOO2() methods.

## A general-purpose cumulative adder:
cadd <- function(x) Reduce("+", x, accumulate = TRUE)
cadd(seq_len(7))

## A simple function to compute continued fractions:
cfrac <- function(x) Reduce(function(u, v) u + 1/v, x, right = TRUE)

## Continued fraction approximation for pi:
cfrac(c(3, 7, 15, 1, 292))

## Continued fraction approximation for Euler's number (e):
cfrac(c(2, 1, 2, 1, 4, 1, 6, 1, 8))

## Iterative function application:
Funcall <- function(f, ...) f(...)
## Compute log(exp(acos(cos(0))))
Reduce(Funcall, list(log, exp, acos, cos), 0, right = TRUE)

## n-fold iterate of a function, functional style:
Iterate <- function(f, n = 1)
  function(x) Reduce(Funcall, rep.int(list(f), n), x, right = TRUE)

## Continued fraction approximation to the golden ratio:
Iterate(function(x) 1 + 1 / x, 30)(1)
## which is the same as
cfrac(rep.int(1, 31))

## Computing square root approximations for x as fixed points of the
## function t |-> (t + x / t) / 2, as a function of the initial value:
asqrt <- function(x, n) Iterate(function(t) (t + x / t) / 2, n)
asqrt(2, 30)(10) # Starting from a positive value => +sqrt(2)
asqrt(2, 30)(-1) # Starting from a negative value => -sqrt(2)

## A list of all functions in the base environment:
funs <- Filter(is.function, sapply(ls(baseenv()), get, baseenv()))

## Functions in base with more than 10 arguments:
names(Filter(function(f) length(formals(f)) > 10, funs))

## Number of functions in base with a '...' argument:
length(Filter(function(f)
  any(names(formals(f)) %in% "..."),
  funs))

## Find all objects in the base environment which are *not* functions:
Filter(Negate(is.function), sapply(ls(baseenv()), get, baseenv()))

---

### gc

**Garbage Collection**

A call of gc causes a garbage collection to take place. gcinfo sets a flag so that automatic collection is either silent (verbose = FALSE) or prints memory usage statistics (verbose = TRUE).

#### Usage

gc(verbos = getOption("verbose"), reset = FALSE, full = TRUE)
gcinfo(verbos)
gc

Arguments

verbose logical; if TRUE, the garbage collection prints statistics about cons cells and the space allocated for vectors.
reset logical; if TRUE the values for maximum space used are reset to the current values.
full logical; if TRUE a full collection is performed; otherwise only more recently allocated objects may be collected.

Details

A call of gc causes a garbage collection to take place. This will also take place automatically without user intervention, and the primary purpose of calling gc is for the report on memory usage. For an accurate report full = TRUE should be used.

It can be useful to call gc after a large object has been removed, as this may prompt R to return memory to the operating system.

R allocates space for vectors in multiples of 8 bytes: hence the report of "Vcells", a relic of an earlier allocator (that used a vector heap).

When gcinfo(TRUE) is in force, messages are sent to the message connection at each garbage collection of the form

   Garbage collection 12 = 10+0+2 (level 0) ...
   6.4 Mbytes of cons cells used (58%)
   2.0 Mbytes of vectors used (32%)

Here the last two lines give the current memory usage rounded up to the next 0.1Mb and as a percentage of the current trigger value. The first line gives a breakdown of the number of garbage collections at various levels (for an explanation see the ‘R Internals’ manual).

Value

gc returns a matrix with rows "Ncells" (cons cells), usually 28 bytes each on 32-bit systems and 56 bytes on 64-bit systems, and "Vcells" (vector cells, 8 bytes each), and columns "used" and "gc trigger", each also interpreted in megabytes (rounded up to the next 0.1Mb).

If maxima have been set for either "Ncells" or "Vcells", a fifth column is printed giving the current limits in Mb (with NA denoting no limit).

The final two columns show the maximum space used since the last call to gc(reset = TRUE) (or since R started).

gcinfo returns the previous value of the flag.

See Also

The ‘R Internals’ manual.
Memory on R’s memory management, and gctorture if you are an R developer.
gc.time() reports time used for garbage collection.
reg.finalizer for actions to happen at garbage collection.
Examples

```r
gc() #- do it now
gcinfo(TRUE) #-- in the future, show when R does it
## vvvvv use larger to *show* something
x <- integer(100000); for(i in 1:18) x <- c(x, i)
gcinfo(verbos = FALSE) #-- don't show it anymore

gc(TRUE)

gc(reset = TRUE)
```

---

**gc.time**

*Report Time Spent in Garbage Collection*

**Description**

This function reports the time spent in garbage collection so far in the R session while GC timing was enabled.

**Usage**

```r
gc.time(on = TRUE)
```

**Arguments**

- `on` logical; if TRUE, GC timing is enabled.

**Details**

Due to timer resolution this may be under-estimate.

This is a *primitive*.

**Value**

A numerical vector of length 5 giving the user CPU time, the system CPU time, the elapsed time and children’s user and system CPU times (normally both zero), of time spent doing garbage collection whilst GC timing was enabled.

Times of child processes are not available on Windows and will always be given as `NA`.

**See Also**

- `gc`, `proc.time` for the timings for the session.

**Examples**

```r
gc.time()
```
Description

Provokes garbage collection on (nearly) every memory allocation. Intended to ferret out memory protection bugs. Also makes R run very slowly, unfortunately.

Usage

gctorture(on = TRUE)
gctorture2(step, wait = step, inhibit_release = FALSE)

Arguments
	on logical; turning it on/off.
step integer; run GC every step allocations; step = 0 turns the GC torture off.
wait integer; number of allocations to wait before starting GC torture.
inhibit_release logical; do not release free objects for re-use: use with caution.

Details

Calling gctorture(TRUE) instructs the memory manager to force a full GC on every allocation. gctorture2 provides a more refined interface that allows the start of the GC torture to be deferred and also gives the option of running a GC only every step allocations.

The third argument to gctorture2 is only used if R has been configured with a strict write barrier enabled. When this is the case all garbage collections are full collections, and the memory manager marks free nodes and enables checks in many situations that signal an error when a free node is used. This can help greatly in isolating unprotected values in C code. It does not detect the case where a node becomes free and is reallocated. The inhibit_release argument can be used to prevent such reallocation. This will cause memory to grow and should be used with caution and in conjunction with operating system facilities to monitor and limit process memory use.

gctorture2 can also be invoked via environment variables at the start of the R session. R_GCTORTURE corresponds to the step argument, R_GCTORTURE_WAIT to wait, and R_GCTORTURE_INHIBIT_RELEASE to inhibit_release.

Value

Previous value of first argument.

Author(s)

Peter Dalgaard and Luke Tierney
get

Return the Value of a Named Object

Description

Search by name for an object (get) or zero or more objects (mget).

Usage

get(x, pos = -1, envir = as.environment(pos), mode = "any", inherits = TRUE)

mget(x, envir = as.environment(-1), mode = "any", ifnotfound, inherits = FALSE)

dynGet(x, ifnotfound = , minframe = 1L, inherits = FALSE)

Arguments

x
For get, an object name (given as a character string or a symbol).
For mget, a character vector of object names.

pos, envir
where to look for the object (see ‘Details’); if omitted search as if the name of the object appeared unquoted in an expression.

mode
the mode or type of object sought: see the ‘Details’ section.

inherits
should the enclosing frames of the environment be searched?

ifnotfound
For mget, a list of values to be used if the item is not found: it will be coerced to a list if necessary.
For dynGet any R object, e.g., a call to stop().

minframe
integer specifying the minimal frame number to look into.

Details

The pos argument can specify the environment in which to look for the object in any of several ways: as a positive integer (the position in the search list); as the character string name of an element in the search list; or as an environment (including using sys.frame to access the currently active function calls). The default of -1 indicates the current environment of the call to get. The envir argument is an alternative way to specify an environment.

These functions look to see if each of the name(s) x have a value bound to it in the specified environment. If inherits is TRUE and a value is not found for x in the specified environment, the enclosing frames of the environment are searched until the name x is encountered. See environment and the ‘R Language Definition’ manual for details about the structure of environments and their enclosures.

If mode is specified then only objects of that type are sought. mode here is a mixture of the meanings of typeof and mode: “function” covers primitive functions and operators, “numeric”, “integer” and “double” all refer to any numeric type, “symbol” and “name” are equivalent but "language" must be used (and not "call" or ")”.

For mget, the values of mode and ifnotfound can be either the same length as x or of length 1. The argument ifnotfound must be a list containing either the value to use if the requested item is not found or a function of one argument which will be called if the item is not found, with argument the name of the item being requested.
dynGet() is somewhat experimental and to be used inside another function. It looks for an object in the callers, i.e., the sys.frame()s of the function. Use with caution.

Value

For get, the object found. If no object is found an error results.
For mget, a named list of objects (found or specified via ifnotfound).

Note

The reverse (or “inverse”) of a <-get(nam) is assign(nam,a), assigning a to name nam.
inherits = TRUE is the default for get in R but not for S where it had a different meaning.

References

See Also

exists for checking whether an object exists; get0 for an efficient way of both checking existence and getting an object.
assign, the inverse of get(), see above.
Use getAnywhere for searching for an object anywhere, including in other namespaces, and getFromNamespace to find an object in a specific namespace.

Examples

get("%o%")

## test mget
e1 <- new.env()
mget(letters, e1, ifnotfound = as.list(LETTERS))

dynGet() is somewhat experimental and to be used inside another function. It looks for an object in the callers, i.e., the sys.frame()s of the function. Use with caution.

Value

For get, the object found. If no object is found an error results.
For mget, a named list of objects (found or specified via ifnotfound).

Note

The reverse (or “inverse”) of a <-get(nam) is assign(nam,a), assigning a to name nam.
inherits = TRUE is the default for get in R but not for S where it had a different meaning.

Examples

get("%o%")

## test mget
e1 <- new.env()
mget(letters, e1, ifnotfound = as.list(LETTERS))

getDLLRegisteredRoutines

*Reflectance Information for C/Fortran routines in a DLL*

Description

This function allows us to query the set of routines in a DLL that are registered with R to enhance dynamic lookup, error handling when calling native routines, and potentially security in the future. This function provides a description of each of the registered routines in the DLL for the different interfaces, i.e. .C, .Call, .Fortran and .External.

Usage

getDLLRegisteredRoutines(dll, addNames = TRUE)
Arguments

dll a character string or DLLInfo object. The character string specifies the file name of the DLL of interest, and is given without the file name extension (e.g., the ‘.dll’ or ‘.so’) and with no directory/path information. So a file ‘MyPackage/libs/MyPackage.so’ would be specified as ‘MyPackage’.

The DLLInfo objects can be obtained directly in calls to dyn.load and library.dynam, or can be found after the DLL has been loaded using getLoadedDLLs, which returns a list of DLLInfo objects (index-able by DLL file name).

The DLLInfo approach avoids any ambiguities related to two DLLs having the same name but corresponding to files in different directories.

addNames a logical value. If this is TRUE, the elements of the returned lists are named using the names of the routines (as seen by R via registration or raw name). If FALSE, these names are not computed and assigned to the lists. As a result, the call should be quicker. The name information is also available in the NativeSymbolInfo objects in the lists.

Details

This takes the registration information after it has been registered and processed by the R internals. In other words, it uses the extended information.

There is print methods for the class, which prints only the types which have registered routines.

Value

A list of class "DLLRegisteredRoutines" with four elements corresponding to the routines registered for the .C, .Call, .Fortran and .External interfaces. Each is a list (of class "NativeRoutineList") with as many elements as there were routines registered for that interface.

Each element identifies a routine and is an object of class "NativeSymbolInfo". An object of this class has the following fields:

name the registered name of the routine (not necessarily the name in the C code).

address the memory address of the routine as resolved in the loaded DLL. This may be NULL if the symbol has not yet been resolved.

dll an object of class DLLInfo describing the DLL. This is same for all elements returned.

numParameters the number of arguments the native routine is to be called with.

Duncan Temple Lang <duncan@wald.ucdavis.edu>

References

‘Writing R Extensions’ manual for symbol registration.

See Also

getLoadedDLLs, getNativeSymbolInfo for information on the entry points listed.
getLoadedDLLs

Examples

dlls <- getLoadedDLLs()
getDLLRegisteredRoutines(dlls["base"])
getDLLRegisteredRoutines("stats")

Description

This function provides a way to get a list of all the DLLs (see `dyn.load`) that are currently loaded in the R session.

Usage

getLoadedDLLs()

Details

This queries the internal table that manages the DLLs.

Value

An object of class "DLLInfoList" which is a list with an element corresponding to each DLL that is currently loaded in the session. Each element is an object of class "DLLInfo" which has the following entries.

name the abbreviated name.
path the fully qualified name of the loaded DLL.
dynamicLookup a logical value indicating whether R uses only the registration information to resolve symbols or whether it searches the entire symbol table of the DLL.
handle a reference to the C-level data structure that provides access to the contents of the DLL. This is an object of class "DLLHandle".

Note that the class DLLInfo has a method for $ which can be used to resolve native symbols within that DLL. Therefore, one must access the R-level elements described above using [[, e.g. x["name"] or x["handle"].

Note

We are starting to use the handle elements in the DLL object to resolve symbols more directly in R.

getDLLRegisteredRoutines, getNativeSymbolInfo
getNativeSymbolInfo

Obtain a Description of one or more Native (C/Fortran) Symbols

Description

This finds and returns a description of one or more dynamically loaded or ‘exported’ built-in native symbols. For each name, it returns information about the name of the symbol, the library in which it is located and, if available, the number of arguments it expects and by which interface it should be called (i.e. `.Call`, `.C`, `.Fortran`, or `.External`). Additionally, it returns the address of the symbol and this can be passed to other C routines. Specifically, this provides a way to explicitly share symbols between different dynamically loaded package libraries. Also, it provides a way to query where symbols were resolved, and aids diagnosing strange behavior associated with dynamic resolution.

Usage

getNativeSymbolInfo(name, PACKAGE, unlist = TRUE, withRegistrationInfo = FALSE)

Arguments

name the name(s) of the native symbol(s).

PACKAGE an optional argument that specifies to which DLL to restrict the search for this symbol. If this is “base”, we search in the R executable itself.

unlist a logical value which controls how the result is returned if the function is called with the name of a single symbol. If unlist is TRUE and the number of symbol names in name is one, then the NativeSymbolInfo object is returned. If it is FALSE, then a list of NativeSymbolInfo objects is returned. This is ignored if the number of symbols passed in name is more than one. To be compatible with earlier versions of this function, this defaults to TRUE.

withRegistrationInfo a logical value indicating whether, if TRUE, to return information that was registered with R about the symbol and its parameter types if such information is available, or if FALSE to return just the address of the symbol.

Details

This uses the same mechanism for resolving symbols as is used in all the native interfaces (.Call, etc.). If the symbol has been explicitly registered by the DLL in which it is contained, information about the number of arguments and the interface by which it should be called will be returned. Otherwise, a generic native symbol object is returned.
**Value**

Generally, a list of `NativeSymbolInfo` elements whose elements can be indexed by the elements of `name` in the call. Each `NativeSymbolInfo` object is a list containing the following elements:

- **name**: the name of the symbol, as given by the `name` argument.
- **address**: if `withRegistrationInfo` is FALSE, this is the native memory address of the symbol which can be used to invoke the routine, and also to compare with other symbol addresses. This is an external pointer object and of class `NativeSymbol`. If `withRegistrationInfo` is TRUE and registration information is available for the symbol, then this is an object of class `RegisteredNativeSymbol` and is a reference to an internal data type that has access to the routine pointer and registration information. This too can be used in calls to `.Call`, `.C`, `.Fortran` and `.External`.
- **dll**: a list containing 3 elements:
  - **name**: the short form of the library name which can be used as the value of the PACKAGE argument in the different native interface functions.
  - **path**: the fully qualified name of the DLL.
  - **dynamicLookup**: a logical value indicating whether dynamic resolution is used when looking for symbols in this library, or only registered routines can be located.

If the routine was explicitly registered by the dynamically loaded library, the list contains a fourth field

- **numParameters**: the number of arguments that should be passed in a call to this routine.

Additionally, the list will have an additional class, being `CRoutine`, `CallRoutine`, `FortranRoutine` or `ExternalRoutine` corresponding to the R interface by which it should be invoked.

If any of the symbols is not found, an error is raised.

If `name` contains only one symbol name and `unlist` is TRUE, then the single `NativeSymbolInfo` is returned rather than the list containing that one element.

**Note**

The third element of the `NativeSymbolInfo` objects was renamed from `package` to `dll` in R version 3.6.0, for consistency with the names of the `NativeSymbolInfo` objects returned by `getDLLRegisteredRoutines()`.

**Note**

One motivation for accessing this reflectance information is to be able to pass native routines to C routines as function pointers in C. This allows us to treat native routines and R functions in a similar manner, such as when passing an R function to C code that makes callbacks to that function at different points in its computation (e.g., `n1s`). Additionally, we can resolve the symbol just once and avoid resolving it repeatedly or using the internal cache.

Duncan Temple Lang

### gettext

Translate Text Messages

#### Description

If Native Language Support was enabled in this build of R, attempt to translate character vectors or set where the translations are to be found.

#### Usage

```r
ggettext(..., domain = NULL)
ngettext(n, msg1, msg2, domain = NULL)
bindtextdomain(domain, dirname = NULL)
```

#### Arguments

- `...`: One or more character vectors.
- `domain`: The ‘domain’ for the translation.
- `n`: a non-negative integer.
- `msg1`: the message to be used in English for \( n = 1 \).
- `msg2`: the message to be used in English for \( n = 0, 2, 3, \ldots \).
- `dirname`: The directory in which to find translated message catalogs for the domain.

#### Details

If `domain` is `NULL` or `""`, and `gettext` or `ngettext` is called from a function in the namespace of package `pkg` the domain is set to "R-pkg". Otherwise there is no default domain.

If a suitable domain is found, each character string is offered for translation, and replaced by its translation into the current language if one is found. The value (logical) NA suppresses any translation.

Conventionally the domain for R warning/error messages in package `pkg` is "R-pkg", and that for C-level messages is "pkg".

For `gettext`, leading and trailing whitespace is ignored when looking for the translation.

`ngettext` is used where the message needs to vary by a single integer. Translating such messages is subject to very specific rules for different languages: see the GNU Gettext Manual. The string will often contain a single instance of `%d` to be used in `sprintf`. If English is used, `msg1` is returned if \( n = 1 \) and `msg2` in all other cases.

#### See Also

`getDLLRegisteredRoutines, is.loaded, .C, .Fortran, .External, .Call, dyn.load`
bindtextdomain is a wrapper for the C function of the same name: your system may have a man
page for it. With a non-NULL dirname it specifies where to look for message catalogues: with
domain = NULL it returns the current location.

Value

For gettext, a character vector, one element per string in .... If translation is not enabled or no
domain is found or no translation is found in that domain, the original strings are returned.

For ngettext, a character string.

For bindtextdomain, a character string giving the current base directory, or NULL if setting it failed.

See Also

stop and warning make use of gettext to translate messages.

xgettext for extracting translatable strings from R source files.

Examples

bindtextdomain("R") # non-null if and only if NLS is enabled

for(n in 0:3)
  print(sprintf(ngettext(n, "%d variable has missing values",
                 "%d variables have missing values"),
               n))

## Not run:
## for translation, those strings should appear in R-pkg.pot as
msgid "%d variable has missing values"
msgid_plural "%d variables have missing values"
msgstr[0] ""
msgstr[1] ""

## End(Not run)

miss <- c("one", "or", "another")
cat(ngettext(length(miss), "variable", "variables"),
    paste(sQuote(miss), collapse = ", "),
    ngettext(length(miss), "contains", "contain"), "missing values
")

## better for translators would be to use
cat(sprintf(ngettext(length(miss),
                 "variable %s contains missing values\n",
                 "variables %s contain missing values\n"),
                 paste(sQuote(miss), collapse = ", ")))

getwd  Get or Set Working Directory

Description

getwd returns an absolute filepath representing the current working directory of the R process;
setwd(dir) is used to set the working directory to dir.
Usage

getwd()
setwd(dir)

Arguments

dir A character string: tilde expansion will be done.

Details

See files for how file paths with marked encodings are interpreted.

Value

getwd returns a character string or NULL if the working directory is not available. On Windows the path returned will use / as the path separator and be encoded in UTF-8. The path will not have a trailing / unless it is the root directory (of a drive or share on Windows).

setwd returns the current directory before the change, invisibly and with the same conventions as getwd. It will give an error if it does not succeed (including if it is not implemented).

Note

Note that the return value is said to be an absolute filepath: there can be more than one representation of the path to a directory and on some OSes the value returned can differ after changing directories and changing back to the same directory (for example if symbolic links have been traversed).

See Also

list.files for the contents of a directory.
normalizePath for a ‘canonical’ path name.

Examples

(WD <- getwd())
if (!is.null(WD)) setwd(WD)

gl Generate Factor Levels

Description

Generate factors by specifying the pattern of their levels.

Usage

gl(n, k, length = n*k, labels = seq_len(n), ordered = FALSE)
Arguments

- **n**: an integer giving the number of levels.
- **k**: an integer giving the number of replications.
- **length**: an integer giving the length of the result.
- **labels**: an optional vector of labels for the resulting factor levels.
- **ordered**: a logical indicating whether the result should be ordered or not.

Value

The result has levels from 1 to **n** with each value replicated in groups of length **k** out to a total length of **length**.

gl is modelled on the GLIM function of the same name.

See Also

The underlying *factor()*.

Examples

```r
## First control, then treatment:
gl(2, 8, labels = c("Control", "Treat"))
## 20 alternating 1s and 2s
gl(2, 1, 20)
## alternating pairs of 1s and 2s
gl(2, 2, 20)
```

Description

*grep*, *grepl*, *gregexpr*, *gregexpr* and *regexec* search for matches to argument pattern within each element of a character vector: they differ in the format of and amount of detail in the results. *sub* and *gsub* perform replacement of the first and all matches respectively.

Usage

```r
grep(pattern, x, ignore.case = FALSE, perl = FALSE, value = FALSE, fixed = FALSE, useBytes = FALSE, invert = FALSE)
grepl(pattern, x, ignore.case = FALSE, perl = FALSE, fixed = FALSE, useBytes = FALSE)
sub(pattern, replacement, x, ignore.case = FALSE, perl = FALSE, fixed = FALSE, useBytes = FALSE)
gsub(pattern, replacement, x, ignore.case = FALSE, perl = FALSE, fixed = FALSE, useBytes = FALSE)
regexpr(pattern, text, ignore.case = FALSE, perl = FALSE,
```

fixed = FALSE, useBytes = FALSE)
gregexpr(pattern, text, ignore.case = FALSE, perl = FALSE,
fixed = FALSE, useBytes = FALSE)
regexec(pattern, text, ignore.case = FALSE, perl = FALSE,
fixed = FALSE, useBytes = FALSE)

Arguments

pattern character string containing a regular expression (or character string for fixed = TRUE) to be matched in the given character vector. Coerced by as.character to a character string if possible. If a character vector of length 2 or more is supplied, the first element is used with a warning. Missing values are allowed except for regexpr, gregexpr and regexec.
x, text a character vector where matches are sought, or an object which can be coerced by as.character to a character vector. Long vectors are supported.
ignore.case if FALSE, the pattern matching is case sensitive and if TRUE, case is ignored during matching.
perl logical. Should Perl-compatible regexps be used?
value if FALSE, a vector containing the (integer) indices of the matches determined by grep is returned, and if TRUE, a vector containing the matching elements themselves is returned.
fixed logical. If TRUE, pattern is a string to be matched as is. Overrides all conflicting arguments.
useBytes logical. If TRUE the matching is done byte-by-byte rather than character-by-character. See ‘Details’.
invert logical. If TRUE return indices or values for elements that do not match.
replacement a replacement for matched pattern in sub and gsub. Coerced to character if possible. For fixed = FALSE this can include backreferences "\1" to "\9" to parenthesized subexpressions of pattern. For perl = TRUE only, it can also contain "\U" or "\L" to convert the rest of the replacement to upper or lower case and "\E" to end case conversion. If a character vector of length 2 or more is supplied, the first element is used with a warning. If NA, all elements in the result corresponding to matches will be set to NA.

Details

Arguments which should be character strings or character vectors are coerced to character if possible.

Each of these functions operates in one of three modes:

1. fixed = TRUE: use exact matching.
2. perl = TRUE: use Perl-style regular expressions.
3. fixed = FALSE, perl = FALSE: use POSIX 1003.2 extended regular expressions (the default).

See the help pages on regular expression for details of the different types of regular expressions.
The two *sub functions differ only in that sub replaces only the first occurrence of a pattern whereas gsub replaces all occurrences. If replacement contains backreferences which are not defined in pattern the result is undefined (but most often the backreference is taken to be "").
For `regexpr`, `gregexpr` and `regexec` it is an error for `pattern` to be `NA`, otherwise `NA` is permitted and gives an `NA` match.

Both `grep` and `grepl` take missing values in `x` as not matching a non-missing pattern.

The main effect of `useBytes = TRUE` is to avoid errors/warnings about invalid inputs and spurious matches in multibyte locales, but for `regexpr` it changes the interpretation of the output. It inhibits the conversion of inputs with marked encodings, and is forced if any input is found which is marked as “bytes” (see Encoding).

Caseless matching does not make much sense for bytes in a multibyte locale, and you should expect it only to work for ASCII characters if `useBytes = TRUE`.

`regexpr` and `gregexpr` with `perl = TRUE` allow Python-style named captures, but not for long vector inputs.

Invalid inputs in the current locale are warned about up to 5 times.

Caseless matching with `perl = TRUE` for non-ASCII characters depends on the PCRE library being compiled with ‘Unicode property support’, which PCRE2 is by default.

**Value**

grep(value = FALSE) returns a vector of the indices of the elements of `x` that yielded a match (or not, for `invert = TRUE`). This will be an integer vector unless the input is a long vector, when it will be a double vector.

grep(value = TRUE) returns a character vector containing the selected elements of `x` (after coercion, preserving names but no other attributes).

`grepl` returns a logical vector (match or not for each element of `x`).

`sub` and `gsub` return a character vector of the same length and with the same attributes as `x` (after possible coercion to character). Elements of character vectors `x` which are not substituted will be returned unchanged (including any declared encoding). If `useBytes = FALSE` a non-ASCII substituted result will often be in UTF-8 with a marked encoding (e.g., if there is a UTF-8 input, and in a multibyte locale unless `fixed = TRUE`). Such strings can be re-encoded by `enc2native`.

`regexpr` returns an integer vector of the same length as `text` giving the starting position of the first match or `−1` if there is none, with attribute “match.length”, an integer vector giving the length of the matched text (or `−1` for no match). The match positions and lengths are in characters unless `useBytes = TRUE` is used, when they are in bytes (as they are for ASCII-only matching: in either case an attribute `useBytes` with value `TRUE` is set on the result). If named capture is used there are further attributes “capture.start”, “capture.length” and “capture.names”.

`gregexpr` returns a list of the same length as `text` each element of which is of the same form as the return value for `regexpr`, except that the starting positions of every (disjoint) match are given.

`regexec` returns a list of the same length as `text` each element of which is either `−1` if there is no match, or a sequence of integers with the starting positions of the match and all subexpressions corresponding to parenthesized subexpressions of `pattern`, with attribute “match.length” a vector giving the lengths of the matches (or `−1` for no match). The interpretation of positions and length and the attributes follows `regexpr`.

Where matching failed because of resource limits (especially for `perl = TRUE`) this is regarded as a non-match, usually with a warning.

**Warning**

The POSIX 1003.2 mode of `gsub` and `gregexpr` does not work correctly with repeated word-boundaries (e.g., `pattern = \b`). Use `perl = TRUE` for such matches (but that may not work as expected with non-ASCII inputs, as the meaning of ‘word’ is system-dependent).
Performance considerations

If you are doing a lot of regular expression matching, including on very long strings, you will want to consider the options used. Generally perl = TRUE will be faster than the default regular expression engine, and fixed = TRUE faster still (especially when each pattern is matched only a few times).

If you are working in a single-byte locale and have marked UTF-8 strings that are representable in that locale, convert them first as just one UTF-8 string will force all the matching to be done in Unicode, which attracts a penalty of around 3 × for the default POSIX 1003.2 mode.

If you can make use of useBytes = TRUE, the strings will not be checked before matching, and the actual matching will be faster. Often byte-based matching suffices in a UTF-8 locale since byte patterns of one character never match part of another.

PCRE-based matching by default used to put additional effort into ‘studying’ the compiled pattern when x/text has length 10 or more. That study may use the PCRE JIT compiler on platforms where it is available (see pcre_config). As from PCRE2 (PCRE version >= 10.00 as reported by extSoftVersion), there is no study phase, but the patterns are optimized automatically when possible, and PCRE JIT is used when enabled. The details are controlled by options PCRE_study and PCRE_use_JIT. (Some timing comparisons can be seen by running file ‘tests/PCRE.R’ in the R sources (and perhaps installed).) People working with PCRE and very long strings can adjust the maximum size of the JIT stack by setting environment variable R_PCRE_JIT_STACK_MAXSIZE before JIT is used to a value between 1 and 1000 in MB: the default is 64. When JIT is not used with PCRE version < 10.30 (that is with PCRE1 and old versions of PCRE2), it might also be wise to set the option PCRE_limit_recursion.

Source

The C code for POSIX-style regular expression matching has changed over the years. As from R 2.10.0 (Oct 2009) the TRE library of Ville Laurikari (https://laurikari.net/tre/) is used. The POSIX standard does give some room for interpretation, especially in the handling of invalid regular expressions and the collation of character ranges, so the results will have changed slightly over the years.

For Perl-style matching PCRE2 or PCRE (https://www.pcre.org) is used: again the results may depend (slightly) on the version of PCRE in use.

### Examples

grep("[a-z]", letters)

txt <- c("arm","foot","lefroo", "bafoobar")
if(length(i <- grep("foo", txt)))
  cat("'foo' appears at least once in\n\t", txt, \"\n\")
i # 2 and 4

txt[i]

## Double all 'a' or 'b's; \" must be escaped, i.e., 'doubled'
gsub("([^ab])", \"\1_\1\", "abc and ABC")

## Using grep1() for filtering
## Find functions with argument names matching "warn":
findArgs <- function(env, pattern) {
  nms <- ls(envir = as.environment(env))
  nms <- nms[is.na(match(nms, c("F","T")))]
  aa <- sapply(nms, function(.) { o <- get(.)
    if(is.function(o)) names(formals(o)) })
  iw <- sapply(aa, function(a) any(grepl(pattern, a, ignore.case=TRUE)))
  aa[iw]
}

### Examples

grep("[a-z]", letters)

txt <- c("arm","foot","lefroo", "bafoobar")
if(length(i <- grep("foo", txt)))
  cat("'foo' appears at least once in\n\t", txt, \"\n\")
i # 2 and 4

txt[i]

## Double all 'a' or 'b's; \" must be escaped, i.e., 'doubled'
gsub("([^ab])", \"\1_\1\", "abc and ABC")

## Using grep1() for filtering
## Find functions with argument names matching "warn":
findArgs <- function(env, pattern) {
  nms <- ls(envir = as.environment(env))
  nms <- nms[is.na(match(nms, c("F","T")))]
  aa <- sapply(nms, function(.) { o <- get(.)
    if(is.function(o)) names(formals(o)) })
  iw <- sapply(aa, function(a) any(grepl(pattern, a, ignore.case=TRUE)))
  aa[iw]
}
findArgs("package:base", "warn")

## trim trailing white space
str <- "Now is the time 
sub(" +"", ",", str) ## spaces only
## what is considered ‘white space’ depends on the locale.
sub([[:space:]]+$", ",", str) ## white space, POSIX-style
## what PCRE considered white space changed in version 8.34: see ?regex
sub("\s+$", ",", str, perl = TRUE) ## PCRE-style white space

## capitalizing
txt <- "a test of capitalizing"
gsub("\\w((\\w*)", "\\\\\\\L\\2", txt, perl=TRUE)
gsub("\\b\\w", "\\\\\\\", txt, perl=TRUE)

txt2 <- "useRs may fly into JFK or laGuardia"
gsub("\\w((\\w*)\\w", "\\\\\\\E\\2\\U\\3", txt2, perl=TRUE)
gsub("\\w((\\w*)\\w", "\\\\\\\E\\2\\U\\3", txt2, perl=TRUE)

## named capture
notables <- c(" Ben Franklin and Jefferson Davis",
" Millard Fillmore")
# name groups 'first' and 'last'
name.rex <- "(?<first>[[:upper:]][[:lower:]]+) (?<last>[[:upper:]][[:lower:]]+)"
(parsed <- regexpr(name.rex, notables, perl = TRUE))
gregexpr(name.rex, notables, perl = TRUE)[[2]]
parse.one <- function(res, result) {
m <- do.call(rbind, lapply(seq_along(res), function(i) {
  if(result[i] == -1) return(""")
  st <- attr(result, "capture.start")[i,]
  substring(res[i], st + attr(result, "capture.length")[i,] - 1)
}))
colnames(m) <- attr(result, "capture.names")
m)
}
parse.one(notables, parsed)

## Decompose a URL into its components.
## Example by LT (http://www.cs.uiowa.edu/~luke/R/regexp.html).
x <- "http://stat.umn.edu:80/xyz"
m <- regexec("^(([^:]+)://)?([^:/]+)(:([^0-9]+))?(/.*)", x)
m
regmatches(x, m)
## Element 3 is the protocol, 4 is the host, 6 is the port, and 7
## is the path. We can use this to make a function for extracting the
## parts of a URL:
URL_parts <- function(x) {
m <- regexec("^(([^:]+)://)?([^:/]+)(:[^0-9]+)?(.*)", x)
parts <- do.call(rbind,
  lapply(regmatches(x, m), `\[`, c(3L, 4L, 6L, 7L)))
colnames(parts) <- c("protocol","host","port","path")
parts
}
URL_parts(x)

## There is no gregexec() yet, but one can emulate it by running
## regexec() on the regmatches obtained via gregexpr(). E.g.:
pattern <- "([[[:alpha:]]]+)([[[:digit:]]]+)"
s <- "Test: A1 BC23 DEF456"
lapply(regmatches(s, gregexpr(pattern, s)),
        function(e) regmatches(e, regexec(pattern, e)))

grepRaw

Pattern Matching for Raw Vectors

Description

grepRaw searches for substring pattern matches within a raw vector x.

Usage

grepRaw(pattern, x, offset = 1L, ignore.case = FALSE,
        value = FALSE, fixed = FALSE, all = FALSE, invert = FALSE)

Arguments

pattern raw vector containing a regular expression (or fixed pattern for fixed = TRUE) to be matched in the given raw vector. Coerced by charToRaw to a character string if possible.
x a raw vector where matches are sought, or an object which can be coerced by charToRaw to a raw vector. Long vectors are not supported.
ignore.case if FALSE, the pattern matching is case sensitive and if TRUE, case is ignored during matching.
offset An integer specifying the offset from which the search should start. Must be positive. The beginning of line is defined to be at that offset so "^^" will match there.
value logical. Determines the return value: see ‘Value’.
fixed logical. If TRUE, pattern is a pattern to be matched as is.
all logical. If TRUE all matches are returned, otherwise just the first one.
invert logical. If TRUE return indices or values for elements that do not match. Ignored (with a warning) unless value = TRUE.

Details

Unlike grep, seeks matching patterns within the raw vector x. This has implications especially in the all = TRUE case, e.g., patterns matching empty strings are inherently infinite and thus may lead to unexpected results.

The argument invert is interpreted as asking to return the complement of the match, which is only meaningful for value = TRUE. Argument offset determines the start of the search, not of the complement. Note that invert = TRUE with all = TRUE will split x into pieces delimited by the pattern including leading and trailing empty strings (consequently the use of regular expressions with "^^" or "$" in that case may lead to less intuitive results).

Some combinations of arguments such as fixed = TRUE with value = TRUE are supported but are less meaningful.
Value

grepRaw(value = FALSE) returns an integer vector of the offsets at which matches have occurred. If all = FALSE then it will be either of length zero (no match) or length one (first matching position).
grepRaw(value = TRUE, all = FALSE) returns a raw vector which is either empty (no match) or the matched part of x.
grepRaw(value = TRUE, all = TRUE) returns a (potentially empty) list of raw vectors corresponding to the matched parts.

Source

The TRE library of Ville Laurikari (https://laurikari.net/tre/) is used except for fixed = TRUE.

See Also

regular expression (aka regexp) for the details of the pattern specification.
grep for matching character vectors.

Examples

grepRaw("no match", "textText") # integer(0): no match
grepRaw("adf", "adadfadfadaadf") # 3 - the first match
grepRaw("adf", "adadfadfadaadf", all=TRUE, fixed=TRUE)
## [1] 3 6 13 -- three matches

Description

Group generic methods can be defined for four pre-specified groups of functions, Math, Ops, Summary and Complex. (There are no objects of these names in base R, but there are in the methods package.)

A method defined for an individual member of the group takes precedence over a method defined for the group as a whole.

Usage

## S3 methods for group generics have prototypes:
Math(x, ...)
Ops(e1, e2)
Complex(z)
Summary(..., na.rm = FALSE)

Arguments

x, z, e1, e2 objects.
... further arguments passed to methods.
na.rm logical: should missing values be removed?
**groupGeneric**

**Details**

There are four groups for which S3 methods can be written, namely the "Math", "Ops", "Summary" and "Complex" groups. These are not R objects in base R, but methods can be supplied for them and base R contains factor, data.frame and difftime methods for the first three groups. (There is also a ordered method for Ops, POSIXt and Date methods for Math and Ops, package_version methods for Ops and Summary, as well as a ts method for Ops in package stats.)

1. Group "Math":
   - abs, sign, sqrt,
     floor, ceiling, trunc,
     round, signif
   - exp, log, expm1, log1p,
     cos, sin, tan,
     cospi, sinpi, tanpi,
     acos, asin, atan
     cosh, sinh, tanh,
     acosh, asinh, atanh
   - lgamma, gamma, digamma, trigamma
   - cumsum, cumprod, cummax, cummin

Members of this group dispatch on x. Most members accept only one argument, but members log, round and signif accept one or two arguments, and trunc accepts one or more.

2. Group "Ops":
   - "+", "-", "+", "/", "+", "/", "/","/"
   - "&", "|", "!
   - "==", "<", ">", ">", ">", ">"

This group contains both binary and unary operators (+, - and !): when a unary operator is encountered the Ops method is called with one argument and e2 is missing.

The classes of both arguments are considered in dispatching any member of this group. For each argument its vector of classes is examined to see if there is a matching specific (preferred) or Ops method. If a method is found for just one argument or the same method is found for both, it is used. If different methods are found, there is a warning about ‘incompatible methods’: in that case or if no method is found for either argument the internal method is used.

Note that the data.frame methods for the comparison ("Compare": ==, <,...) and logic ("Logic": & and |) operators return a logical matrix instead of a data frame, for convenience and back compatibility.

If the members of this group are called as functions, any argument names are removed to ensure that positional matching is always used.

3. Group "Summary":
   - all, any
   - sum, prod
   - min, max
   - range

Members of this group dispatch on the first argument supplied.

Note that the data.frame methods for the "Summary" and "Math" groups require "numeric-alike" columns x, i.e., fulfilling

\[
is.numeric(x) \mid\mid is.logical(x) \mid\mid is.complex(x)\]
4. Group "Complex":

- Arg, Conj, Im, Mod, Re

Members of this group dispatch on \( z \).

Note that a method will be used for one of these groups or one of its members only if it corresponds to a "class" attribute, as the internal code dispatches on \texttt{oldClass} and not on \texttt{class}. This is for efficiency: having to dispatch on, say, \texttt{Ops.integer} would be too slow.

The number of arguments supplied for primitive members of the "Math" group generic methods is not checked prior to dispatch.

There is no lazy evaluation of arguments for group-generic functions.

**Technical Details**

These functions are all primitive and \texttt{internal generic}.

The details of method dispatch and variables such as \texttt{.Generic} are discussed in the help for \texttt{UseMethod}. There are a few small differences:

- For the operators of group \texttt{Ops}, the object \texttt{.Method} is a length-two character vector with elements the methods selected for the left and right arguments respectively. (If no method was selected, the corresponding element is "").

- Object \texttt{.Group} records the group used for dispatch (if a specific method is used this is "").

**Note**

Package \texttt{methods} does contain objects with these names, which it has re-used in confusing similar (but different) ways. See the help for that package.

**References**

**See Also**

\texttt{methods} for methods of non-internal generic functions.

\texttt{S4groupGeneric} for group generics for S4 methods.

**Examples**

```r
require(utils)

d.fr <- data.frame(x = 1:9, y = stats::rnorm(9))
class(1 + d.fr) == "data.frame" #-- add to d.f. ...

methods("Math")
methods("Ops")
methods("Summary")
methods("Complex") # none in base R
```
grouping

Grouping Permutation

Description

grouping returns a permutation which rearranges its first argument such that identical values are adjacent to each other. Also returned as attributes are the group-wise partitioning and the maximum group size.

Usage

grouping(...)

Arguments

...  a sequence of numeric, character or logical vectors, all of the same length, or a classed R object.

Details

The function partially sorts the elements so that identical values are adjacent. NA values come last. This is guaranteed to be stable, so ties are preserved, and if the data are already grouped/sorted, the grouping is unchanged. This is useful for aggregation and is particularly fast for character vectors.

Under the covers, the "radix" method of order is used, and the same caveats apply, including restrictions on character encodings and lack of support for long vectors (those with $2^{31}$ or more elements). Real-valued numbers are slightly rounded to account for numerical imprecision.

Like order, for a classed R object the grouping is based on the result of xtfrm.

Value

An object of class "grouping", the representation of which should be considered experimental and subject to change. It is an integer vector with two attributes:

- ends  subscripts in the result corresponding to the last member of each group
- maxgrp  the maximum group size

See Also

order, xtfrm.

Examples

(ii <- grouping(x <- c(1, 1, 3:1, 1:4, 3), y <- c(9, 9:1), z <- c(2, 1:9)))
## 6 5 2 1 7 4 10 8 3 9
rbind(x, y, z)[, ii]
Description

gzcon provides a modified connection that wraps an existing connection, and decompresses reads or compresses writes through that connection. Standard gzip headers are assumed.

Usage

gzcon(con, level = 6, allowNonCompressed = TRUE, text = FALSE)

Arguments

con     a connection.
level    integer between 0 and 9, the compression level when writing.
allowNonCompressed
          logical. When reading, should non-compressed input be allowed?
text    logical. Should the connection be text-oriented? This is distinct from the mode of the connection (must always be binary). If TRUE, pushBack works on the connection, otherwise readBin and friends apply.

Details

If con is open then the modified connection is opened. Closing the wrapper connection will also close the underlying connection.

Reading from a connection which does not supply a gzip magic header is equivalent to reading from the original connection if allowNonCompressed is true, otherwise an error.

Compressed output will contain embedded NUL bytes, and so con is not permitted to be a textConnection opened with open = "w". Use a writable rawConnection to compress data into a variable.

The original connection becomes unusable: any object pointing to it will now refer to the modified connection. For this reason, the new connection needs to be closed explicitly.

Value

An object inheriting from class "connection". This is the same connection number as supplied, but with a modified internal structure. It has binary mode.

See Also

gzfile

Examples

## Uncompress a data file from a URL
z <- gzcon(url("https://www.stats.ox.ac.uk/pub/datasets/csb/ch12.dat.gz"))
# read.table can only read from a text-mode connection.
raw <- textConnection(readLines(z))
close(z)
dat <- read.table(raw)
close(raw)
dat[1:4,]

## gzfile and gzcon can inter-work. 
## Of course here one would use gzfile, but file() can be replaced by  
## any other connection generator. 
zzfil <- tempfile(fileext = ".gz") 
zz <- gzfile(zzfil, "w")
cat("TITLE extra line", "2 3 5 7", ", "11 13 17", file = zz, sep = "\n")
close(zz)
readLines(zz <- gzcon(file(zzfil, "rb")))
close(zz)
unlink(zzfil)

zzfil2 <- tempfile(fileext = ".gz") 
zz <- gzcon(file(zzfil2, "wb"))
cat("TITLE extra line", "2 3 5 7", ", "11 13 17", file = zz, sep = "\n")
close(zz)
readLines(zz <- gzfile(zzfil2))
close(zz)
unlink(zzfil2)

### hexmode

#### Display Numbers in Hexadecimal

**Description**

Convert or print integers in hexadecimal format, with as many digits as are needed to display the largest, using leading zeroes as necessary.

**Usage**

```r
as.hexmode(x)
```

## S3 method for class 'hexmode'
```r
as.character(x, ...)
```

## S3 method for class 'hexmode'
```r
format(x, width = NULL, upper.case = FALSE, ...)
```

## S3 method for class 'hexmode'
```r
print(x, ...)
```

**Arguments**

- `x` An object, for the methods inheriting from class "hexmode".
- `width` NULL or a positive integer specifying the minimum field width to be used, with padding by leading zeroes.
- `upper.case` a logical indicating whether to use upper-case letters or lower-case letters (default).
- `...` further arguments passed to or from other methods.
Details

Class "hexmode" consists of integer vectors with that class attribute, used merely to ensure that they are printed in hex.

If width = NULL (the default), the output is padded with leading zeroes to the smallest width needed for all the non-missing elements.

as.hexmode can convert integers (of type "integer" or "double") and character vectors whose elements contain only 0-9, a-f, A-F (or are NA) to class "hexmode".

There is a ! method and methods for | and &:
these recycle their arguments to the length of the longer and then apply the operators bitwise to each element.

See Also

octmode, sprintf for other options in converting integers to hex, strtol to convert hex strings to integers.

Examples

```r
i <- as.hexmode("7fffffff")
i; class(i)
identical(as.integer(i), .Machine$integer.max)

hm <- as.hexmode(c(NA, 1)); hm
as.integer(hm)
```

Hyperbolic

Hyperbolic Functions

Description

These functions give the obvious hyperbolic functions. They respectively compute the hyperbolic cosine, sine, tangent, and their inverses, arc-cosine, arc-sine, arc-tangent (or 'area cosine', etc).

Usage

- `cosh(x)`
- `sinh(x)`
- `tanh(x)`
- `acosh(x)`
- `asinh(x)`
- `atanh(x)`

Arguments

- `x` a numeric or complex vector
iconv

Details

These are internal generic primitive functions: methods can be defined for them individually or via
the Math group generic.

Branch cuts are consistent with the inverse trigonometric functions asin \( \text{et seq} \), and agree with those
defined in Abramowitz and Stegun, figure 4.7, page 86. The behaviour actually on the cuts follows
the C99 standard which requires continuity coming round the endpoint in a counter-clockwise di-
rection.

S4 methods

All are S4 generic functions: methods can be defined for them individually or via the Math group
generic.

The trigonometric functions, \( \cos, \sin, \tan \), and their inverses \( \acos, \asin, \atan \).

The logistic distribution function plogis is a shifted version of tanh() for numeric \( x \).

iconv

Convert Character Vector between Encodings

Description

This uses system facilities to convert a character vector between encodings: the ‘i’ stands for ‘in-
ternationalization’.

Usage

iconv(x, from = "", to = "", sub = NA, mark = TRUE, toRaw = FALSE)

iconvlist()

Arguments

x
A character vector, or an object to be converted to a character vector
by as.character, or a list with NULL and raw elements as returned by
iconv(toRaw = TRUE).

from
A character string describing the current encoding.

to
A character string describing the target encoding.

sub
character string. If not NA it is used to replace any non-convertible bytes in
the input. (This would normally be a single character, but can be more.) If
"byte", the indication is "<xx>" with the hex code of the byte. If "Unicode"
and converting from UTF-8, the Unicode point in the form "<U+xxxx>".

mark
logical, for expert use. Should encodings be marked?

toRaw
logical. Should a list of raw vectors be returned rather than a character vector?
Details

The names of encodings and which ones are available are platform-dependent. All R platforms support "" (for the encoding of the current locale), "latin1" and "UTF-8". Generally case is ignored when specifying an encoding.

On most platforms iconvlist provides an alphabetical list of the supported encodings. On others, the information is on the man page for iconv(5) or elsewhere in the man pages (but beware that the system command iconv may not support the same set of encodings as the C functions R calls). Unfortunately, the names are rarely supported across all platforms.

Elements of x which cannot be converted (perhaps because they are invalid or because they cannot be represented in the target encoding) will be returned as NA unless sub is specified.

Most versions of iconv will allow transliteration by appending '//'TRANSLIT' to the to encoding: see the examples.

Encoding "ASCII" is accepted, and on most systems "C" and "POSIX" are synonyms for ASCII.

Any encoding bits (see Encoding) on elements of x are ignored: they will always be translated as if from encoding from even if declared otherwise. enc2native and enc2utf8 provide alternatives which do take declared encodings into account.

Note that implementations of iconv typically do not do much validity checking and will often mis-convert inputs which are invalid in encoding from.

If sub = "Unicode" is used for a non-UTF-8 input it is the same as sub = "byte".

Value

If toRaw = FALSE (the default), the value is a character vector of the same length and the same attributes as x (after conversion to a character vector).

If mark = TRUE (the default) the elements of the result have a declared encoding if to is "latin1" or "UTF-8", or if to = "" and the current locale’s encoding is detected as Latin-1 (or its superset CP1252 on Windows) or UTF-8.

If toRaw = TRUE, the value is a list of the same length and the same attributes as x whose elements are either NULL (if conversion fails) or a raw vector.

For iconvlist(), a character vector (typically of a few hundred elements) of known encoding names.

Implementation Details

There are three main implementations of iconv in use. Linux’s C runtime ‘glibc’ contains one. Several platforms supply GNU ‘libiconv’, including macOS, FreeBSD and Cygwin, in some cases with additional encodings. On Windows we use a version of Yukihiro Nakadaira’s ‘win_iconv’, which is based on Windows’ codepages. (We have added many encoding names for compatibility with other systems.) All three have iconvlist, ignore case in encoding names and support ‘//'TRANSLIT’ (but with different results, and for ‘win_iconv’ currently a ‘best fit’ strategy is used except for to = "ASCII").

Most commercial Unixes contain an implementation of iconv but none we have encountered have supported the encoding names we need: the ‘R Installation and Administration’ manual recommends installing GNU ‘libiconv’ on Solaris and AIX, for example.

There are other implementations, e.g. NetBSD has used one from the Citrus project (which does not support ‘//'TRANSLIT’) and there is an older FreeBSD port (‘libiconv’ is usually used there): it has not been reported whether or not these work with R.

Note that you cannot rely on invalid inputs being detected, especially for to = "ASCII" where some implementations allow 8-bit characters and pass them through unchanged or with transliteration.
Some of the implementations have interesting extra encodings: for example GNU `libiconv` allows to = "C99" to use `\uxxxx` escapes for non-ASCII characters.

**Byte Order Marks**

most commonly known as ‘BOMs’.

Encodings using character units which are more than one byte in size can be written on a file in either big-endian or little-endian order: this applies most commonly to UCS-2, UTF-16 and UTF-32/UCS-4 encodings. Some systems will write the Unicode character U+FEFF at the beginning of a file in these encodings and perhaps also in UTF-8. In that usage the character is known as a BOM, and should be handled during input (see the ‘Encodings’ section under `connection`: re-encoded connections have some special handling of BOMs). The rest of this section applies when this has not been done so `x` starts with a BOM.

Implementations will generally interpret a BOM for `from` given as one of “UCS-2”, “UTF-16” and “UTF-32”. Implementations differ in how they treat BOMs in `x` in other from encodings: they may be discarded, returned as character U+FEFF or regarded as invalid.

**Note**

The only reasonably portable name for the ISO 8859-15 encoding, commonly known as ‘Latin 9’, is "latin-9": some platforms support "latin9" but GNU ‘libiconv’ does not.

Encoding names "utf8", "mac" and "macroman" are not portable. "utf8" is converted to "UTF-8" for from and to by `iconv`, but not for e.g. `fileEncoding` arguments. "macintosh" is the official (and most widely supported) name for ‘Mac Roman’ (https://en.wikipedia.org/wiki/Mac_OS_Roman).

**See Also**

`localeToCharset`, `file`.

**Examples**

```r
## In principle, as not all systems have iconvlist
try(utils::head(iconvlist(), n = 50))

## Not run:
## convert from Latin-2 to UTF-8: two of the glibc iconv variants.
icov(x, "ISO_8859-2", "UTF-8")
icov(x, "LATIN2", "UTF-8")

## End(Not run)

## Both x below are in latin1 and will only display correctly in a
## locale that can represent and display latin1.
x <- "fa\xE7ile"
Encoding(x) <- "latin1"
x
charToRaw(xx <- iconv(x, "latin1", "UTF-8"))
xx

iconv(x, "latin1", "ASCII") # NA
iconv(x, "latin1", "ASCII", "?") # "fa?ile"
icov(x, "latin1", "ASCII", "") # "faile"
icov(x, "latin1", "ASCII", "byte") # "fa<e7>ile"
```
### icuSetCollate

**Setup Collation by ICU**

**Description**

Controls the way collation is done by ICU (an optional part of the R build).

**Usage**

```r
icuSetCollate(...) icuGetCollate(type = c("actual", "valid"))
```

**Arguments**

- `...`: Named arguments, see ‘Details’.
- `type`: character string: can be abbreviated. Either the actual locale in use for collation or the most specific locale which would be valid.

**Details**

Optionally, R can be built to collate character strings by ICU ([http://site.icu-project.org](http://site.icu-project.org)). For such systems, `icuSetCollate` can be used to tune the way collation is done. On other builds calling this function does nothing, with a warning.

Possible arguments are

- `locale`: A character string such as "da_DK" giving the language and country whose collation rules are to be used. If present, this should be the first argument.
- `case_first`: "upper", "lower" or "default", asking for upper- or lower-case characters to be sorted first. The default is usually lower-case first, but not in all languages (not under the default settings for Danish, for example).
- `alternate_handling`: Controls the handling of ‘variable’ characters (mainly punctuation and symbols). Possible values are "non_ignorable" (primary strength) and "shifted" (quaternary strength).
- `strength`: Which components should be used? Possible values "primary", "secondary", "tertiary" (default), "quaternary" and "identical".
- `french_collation`: In a French locale the way accents affect collation is from right to left, whereas in most other locales it is from left to right. Possible values "on", "off" and "default".
normalization: Should strings be normalized? Possible values are "on" and "off" (default).

This affects the collation of composite characters.

case_level: An additional level between secondary and tertiary, used to distinguish large and small Japanese Kana characters. Possible values "on" and "off" (default).

hiragana_quaternary: Possible values "on" (sort Hiragana first at quaternary level) and "off".

Only the first three are likely to be of interest except to those with a detailed understanding of collation and specialized requirements.

Some special values are accepted for locale:

"none": ICU is not used for collation: the OS’s collation services are used instead.

"ASCII": ICU is not used for collation: the C function strcmp is used instead, which should sort byte-by-byte in (unsigned) numerical order.

"default": obtains the locale from the OS as is done at the start of the session. If environment variable R_ICU_LOCALE is set to a non-empty value, its value is used rather than consulting the OS, unless environment variable LC_ALL is set to 'C' (or unset but LC_COLLATE is set to 'C').

"", "root": the ‘root’ collation: see https://www.unicode.org/reports/tr35/tr35-collation.html#Root_Collation.

For the specifications of ‘real’ ICU locales, see http://userguide.icu-project.org/locale. Note that ICU does not report that a locale is not supported, but falls back to its idea of ‘best fit’ (which could be rather different and is reported by icuGetCollate("actual"), often "root"). Most English locales fall back to "root" as although e.g. "en_GB" is a valid locale (at least on some platforms), it contains no special rules for collation. Note that "C" is not a supported ICU locale and hence R_ICU_LOCALE should never be set to "C".

Some examples are case_level = "on", strength = "primary" to ignore accent differences and alternate_handling = "shifted" to ignore space and punctuation characters.

Initially ICU will not be used for collation if the OS is set to use the C locale for collation and R_ICU_LOCALE is not set. Once this function is called with a value for locale, ICU will be used until it is called again with locale = "none". ICU will not be used once Sys.setlocale is called with a "C" value for LC_ALL or LC_COLLATE, even if R_ICU_LOCALE is set. ICU will be used again honoring R_ICU_LOCALE once Sys.setlocale is called to set a different collation order. Environment variables LC_ALL (or LC_COLLATE) take precedence over R_ICU_LOCALE if and only if they are set to 'C'. Due to the interaction with other ways of setting the collation order, R_ICU_LOCALE should be used with care and only when needed.

All customizations are reset to the default for the locale if locale is specified: the collation engine is reset if the OS collation locate category is changed by Sys.setlocale.

Value

For icuGetCollate, a character string describing the ICU locale in use (which may be reported as "ICU not in use"). The ‘actual’ locale may be simpler than the requested locale: for example "da" rather than "da_DK": English locales are likely to report "root".

Note

ICU is used by default wherever it is available: this include macOS, Solaris and many Linux installations. As it works internally in UTF-8, it will be most efficient in UTF-8 locales.

It is optional on Windows: if R has been built against ICU, it will only be used if environment variable R_ICU_LOCALE is set or once icuSetCollate is called to select the locale (as ICU and Windows differ in their idea of locale names). Note that icuSetCollate(locale = "default")
should work reasonably well for \( R \geq 3.2.0 \) and Windows Vista/Server 2008 and later (but finds the system default ignoring environment variables such as LC_COLLATE).

See Also

Comparison, sort.

capabilities for whether ICU is available; extSoftVersion for its version.

The ICU user guide chapter on collation (http://userguide.icu-project.org/collation).

Examples

```r
## These examples depend on having ICU available, and on the locale.
## As we don't know the current settings, we can only reset to the default.
if(capabilities("ICU")) withAutoprint({
  icuGetCollate()
  icuGetCollate("valid")
  x <- c("Aarhus", "aarhus", "safe", "test", "Zoo")
  sort(x)
  icuSetCollate(case_first = "upper"); sort(x)
  icuSetCollate(case_first = "lower"); sort(x)

  ## Danish collates upper-case-first and with 'aa' as a single letter
  icuSetCollate(locale = "da_DK", case_first = "default"); sort(x)

  ## Estonian collates Z between S and T
  icuSetCollate(locale = "et_EE"); sort(x)

  icuSetCollate(locale = "default"); icuGetCollate("valid")
})
```

identical

Test Objects for Exact Equality

Description

The safe and reliable way to test two objects for being exactly equal. It returns TRUE in this case, FALSE in every other case.

Usage

```r
identical(x, y, num.eq = TRUE, single.NA = TRUE, attrib.as.set = TRUE,
         ignore.bytecode = TRUE, ignore.environment = FALSE,
         ignore.srcref = TRUE)
```

Arguments

- **x, y** any \( R \) objects.
- **num.eq** logical indicating if (double and complex non-NA) numbers should be compared using == ("equal"), or by bitwise comparison. The latter (non-default) differentiates between -0 and +0.
- **single.NA** logical indicating if there is conceptually just one numeric NA and one NaN; single.NA = FALSE differentiates bit patterns.
identical

attrib.as.set  logical indicating if attributes of x and y should be treated as unordered tagged pairlists ("sets"); this currently also applies to slots of S4 objects. It may well be too strict to set attrib.as.set = FALSE.

ignore.bytecode  logical indicating if byte code should be ignored when comparing closures.

ignore.environment  logical indicating if their environments should be ignored when comparing closures.

ignore.srcref  logical indicating if their "srcref" attributes should be ignored when comparing closures.

Details

A call to identical is the way to test exact equality in if and while statements, as well as in logical expressions that use && or ||. In all these applications you need to be assured of getting a single logical value.

Users often use the comparison operators, such as == or !=, in these situations. It looks natural, but it is not what these operators are designed to do in R. They return an object like the arguments. If you expected x and y to be of length 1, but it happened that one of them was not, you will not get a single FALSE. Similarly, if one of the arguments is NA, the result is also NA. In either case, the expression if(x == y) .... won't work as expected.

The function all.equal is also sometimes used to test equality this way, but was intended for something different: it allows for small differences in numeric results.

The computations in identical are also reliable and usually fast. There should never be an error. The only known way to kill identical is by having an invalid pointer at the C level, generating a memory fault. It will usually find inequality quickly. Checking equality for two large, complicated objects can take longer if the objects are identical or nearly so, but represent completely independent copies. For most applications, however, the computational cost should be negligible.

If single.NA is true, as by default, identical sees NaN as different from NA_real_, but all NaNs are equal (and all NA of the same type are equal).

Character strings are regarded as identical if they are in different marked encodings but would agree when translated to UTF-8.

If attrib.as.set is true, as by default, comparison of attributes view them as a set (and not a vector, so order is not tested).

If ignore.bytecode is true (the default), the compiled bytecode of a function (see cmpfun) will be ignored in the comparison. If it is false, functions will compare equal only if they are copies of the same compiled object (or both are uncompiled). To check whether two different compiles are equal, you should compare the results of disassemble().

You almost never want to use identical on datetimes of class "POSIXlt": not only can different times in the different time zones represent the same time and time zones have multiple names, but several of the components are optional.

Note that identical(x,y,TRUE,TRUE,FALSE,FALSE) pickily tests for exact equality.

Value

A single logical value, TRUE or FALSE, never NA and never anything other than a single value.

See Also
all.equal for descriptions of how two objects differ; Comparison and Logic for elementwise comparisons.

Examples

identical(1, NULL) ## FALSE -- don’t try this with ==
identical(1, 1.) ## TRUE in R (both are stored as doubles)
identical(1, as.integer(1)) ## FALSE, stored as different types

x <- 1.0; y <- 0.99999999999
## how to test for object equality allowing for numeric fuzz :
(E <- all.equal(x, y))
identical(TRUE, E)
isTRUE(E) # alternative test
## If all.equal thinks the objects are different, it returns a
## character string, and the above expression evaluates to FALSE

## even for unusual R objects :
identical(.GlobalEnv, environment())

### ------- Pickyness Flags : -----------------------------

## the infamous example:
identical(0., -0.) # TRUE, i.e. not differentiated
identical(0., -0., num.eq = FALSE)
## similar:
identical(NaN, -NaN) # TRUE
identical(NaN, -NaN, single.NA = FALSE) # differ on bit-level

### For functions (“closure”s): ----------------------------------------------
### ~~~~~~~~~

f <- function(x) x
f
g <- compiler::cmpfun(f)
g
identical(f, g) # TRUE, as bytecode is ignored by default
identical(f, g, ignore.bytecode=FALSE) # FALSE: bytecode differs

## GLM families contain several functions, some of which share an environment:
p1 <- poisson(); p2 <- poisson()
identical(p1, p2) # FALSE
identical(p1, p2, ignore.environment=TRUE) # TRUE

## in interactive use, the ‘keep.source’ option is typically true:
op <- options(keep.source = TRUE) # and so, these have differing "srcref" :
f1 <- function() {}
f2 <- function() {}
identical(f1,f2)# ignore.srcref= TRUE : TRUE
identical(f1,f2, ignore.srcref=FALSE)# FALSE
options(op) # revert to previous state
**identity**  
*Identity Function*

**Description**
A trivial identity function returning its argument.

**Usage**
```r
identity(x)
```

**Arguments**
- `x` an R object.

**See Also**
- `diag` creates diagonal matrices, including identity ones.

---

**ifelse**  
*Conditional Element Selection*

**Description**
ifelse returns a value with the same shape as test which is filled with elements selected from either yes or no depending on whether the element of test is TRUE or FALSE.

**Usage**
```r
ifelse(test, yes, no)
```

**Arguments**
- `test` an object which can be coerced to logical mode.
- `yes` return values for true elements of test.
- `no` return values for false elements of test.

**Details**
If yes or no are too short, their elements are recycled. yes will be evaluated if and only if any element of test is true, and analogously for no.

Missing values in test give missing values in the result.

**Value**
A vector of the same length and attributes (including dimensions and "class") as test and data values from the values of yes or no. The mode of the answer will be coerced from logical to accommodate first any values taken from yes and then any values taken from no.
Warning

The mode of the result may depend on the value of test (see the examples), and the class attribute (see oldClass) of the result is taken from test and may be inappropriate for the values selected from yes and no.

Sometimes it is better to use a construction such as

\[
(tmp <- yes; tmp[!test] <- no[!test]; tmp)
\]

possibly extended to handle missing values in test.

Further note that if(test) yes else no is much more efficient and often much preferable to ifelse(test, yes, no) whenever test is a simple true/false result, i.e., when length(test) == 1.

The srcRef attribute of functions is handled specially: if test is a simple true result and yes evaluates to a function with srcRef attribute, ifelse returns yes including its attribute (the same applies to a false test and no argument). This functionality is only for backwards compatibility, the form if(test) yes else no should be used whenever yes and no are functions.

if.

Examples

```r
x <- c(6:-4)
sqrt(x) # gives warning
sqrt(ifelse(x >= 0, x, NA)) # no warning

## Note: the following also gives the warning!
ifelse(x >= 0, sqrt(x), NA)
```

```r
## ifelse() strips attributes
## This is important when working with Dates and factors
x <- seq(as.Date("2000-02-29"), as.Date("2004-10-04"), by = "1 month")
## has many "yyyy-mm-29", but a few "yyyy-03-01" in the non-leap years
y <- ifelse(as.POSIXlt(x)$mday == 29, x, NA)
head(y) # not what you expected ... ==> need restore the class attribute:
class(y) <- class(x)
y
## This is a (not atypical) case where it is better *not* to use ifelse(),
## but rather the more efficient and still clear:
y2 <- x
y2[as.POSIXlt(x)$mday != 29] <- NA
## which gives the same as ifelse()+class() hack:
stopifnot(identical(y2, y))
```

```r
## example of different return modes (and 'test' alone determining length):
yes <- 1:3
```
no <- pi^(1:4)
utils::str( ifelse(NA, yes, no) ) # logical, length 1
utils::str( ifelse(TRUE, yes, no) ) # integer, length 1
utils::str( ifelse(FALSE, yes, no) ) # double, length 1

Description

Creates or tests for objects of type "integer".

Usage

integer(length = 0)
as.integer(x, ...)
is.integer(x)

Arguments

length        A non-negative integer specifying the desired length. Double values will be coerced to integer: supplying an argument of length other than one is an error.
x            object to be coerced or tested.
...        further arguments passed to or from other methods.

Details

Integer vectors exist so that data can be passed to C or Fortran code which expects them, and so that (small) integer data can be represented exactly and compactly.

Note that current implementations of R use 32-bit integers for integer vectors, so the range of representable integers is restricted to about ±2 × 10^9: doubles can hold much larger integers exactly.

Value

integer creates a integer vector of the specified length. Each element of the vector is equal to 0.
as.integer attempts to coerce its argument to be of integer type. The answer will be NA unless the coercion succeeds. Real values larger in modulus than the largest integer are coerced to NA (unlike S which gives the most extreme integer of the same sign). Non-integral numeric values are truncated towards zero (i.e., as.integer(x) equals trunc(x) there), and imaginary parts of complex numbers are discarded (with a warning). Character strings containing optional whitespace followed by either a decimal representation or a hexadecimal representation (starting with 0x or 0X) can be converted, as well as any allowed by the platform for real numbers. Like as.vector it strips attributes including names. (To ensure that an object x is of integer type without stripping attributes, use storage.mode(x) <-"integer".)
is.integer returns TRUE or FALSE depending on whether its argument is of integer type or not, unless it is a factor when it returns FALSE.

Note

is.integer(x) does not test if x contains integer numbers! For that, use round, as in the function is.wholenumber(x) in the examples.
interaction

Description
interaction computes a factor which represents the interaction of the given factors. The result of interaction is always unordered.

Usage
interaction(..., drop = FALSE, sep = ".", lex.order = FALSE)

Arguments
... the factors for which interaction is to be computed, or a single list giving those factors.
drop if drop is TRUE, unused factor levels are dropped from the result. The default is to retain all factor levels.
sep string to construct the new level labels by joining the constituent ones.
lex.order logical indicating if the order of factor concatenation should be lexically ordered.

Value
A factor which represents the interaction of the given factors. The levels are labelled as the levels of the individual factors joined by sep which is . by default.
By default, when lex.order = FALSE, the levels are ordered so the level of the first factor varies fastest, then the second and so on. This is the reverse of lexicographic ordering (which you can get by lex.order = TRUE), and differs from ::. (It is done this way for compatibility with S.)
interactive

References

See Also
factor:: where f:g is similar to interaction(f,g,sep = ":") when f and g are factors.

Examples
```r
a <- gl(2, 4, 8)
b <- gl(2, 2, 8, labels = c("ctrl", "treat"))
s <- gl(2, 1, 8, labels = c("M", "F"))
interaction(a, b)
interaction(a, b, s, sep = ":")
stopifnot(identical(a:s,
    interaction(a, s, sep = ":", lex.order = TRUE)),
    identical(a:s:b,
        interaction(a, s, b, sep = ":", lex.order = TRUE)))
```

---

interactive | Is R Running Interactively?
---|---

Description
Return TRUE when R is being used interactively and FALSE otherwise.

Usage
```r
interactive()
```

Details
An interactive R session is one in which it is assumed that there is a human operator to interact with, so for example R can prompt for corrections to incorrect input or ask what to do next or if it is OK to move to the next plot.

GUI consoles will arrange to start R in an interactive session. When R is run in a terminal (via Rterm.exe on Windows), it assumes that it is interactive if `stdin` is connected to a (pseudo-)terminal and not if `stdin` is redirected to a file or pipe. Command-line options `--interactive` (Unix) and `--ess` (Windows, Rterm.exe) override the default assumption. (On a Unix-alike, whether the readline command-line editor is used is not overridden by `--interactive`.)

Embedded uses of R can set a session to be interactive or not.

Internally, whether a session is interactive determines

- how some errors are handled and reported, e.g. see `stop` and `options("showWarnCalls")`.
- whether one of `--save`, `--no-save` or `--vanilla` is required, and if R ever asks whether to save the workspace.
- the choice of default graphics device launched when needed and by `dev.new`: see `options("device")`
- whether graphics devices ever ask for confirmation of a new page.

In addition, R's own R code makes use of `interactive()`: for example `help`, `debugger` and `install.packages` do.
Note
This is a primitive function.

source, .First

Examples
.First <- function() if(interactive()) x11()

Internal Call an Internal Function

Description
.Internal performs a call to an internal code which is built in to the R interpreter. Only true R wizards should even consider using this function, and only R developers can add to the list of internal functions.

Usage
.Internal(call)

Arguments
call a call expression

See Also
.Primitive, .External (the nearest equivalent available to users).

Description
Many R-internal functions are generic and allow methods to be written for.
Details

The following primitive and internal functions are *generic*, i.e., you can write *methods* for them:

\[
[. \\
[[. \\
$. \\
[<-. \\
[[<-. \\
$<-. \\
length, \\
length<-. \\
lengths, \\
dimnames, \\
dimnames<-. \\
dim, \\
dim<-. \\
names, \\
names<-. \\
levels<-. \\
@<-. \\
c, \\
unlist, cbind, rbind, \\
as.character, \\
as.complex, \\
as.double, \\
as.integer, \\
as.logical, \\
as.raw, \\
as.vector, \\
as.call, \\
as.environment \\
is.array, \\
is.matrix, \\
is.na, \\
anyNA, \\
is.nan, \\
is.finite \\
is.infinite \\
is.numeric, \\
nchar \\
rep,
\]
rep.int
rep_len
seq.int (which dispatches methods for "seq"),
is.unsorted and
xtfrm

In addition, \texttt{is.name} is a synonym for \texttt{is.symbol} and dispatches methods for the latter. Similarly, \texttt{as.numeric} is a synonym for \texttt{as.double} and dispatches methods for the latter, i.e., S3 methods are for \texttt{as.double}, whereas S4 methods are to be written for \texttt{as.numeric}.

Note that all of the \texttt{group generic} functions are also internal/primitive and allow methods to be written for them.

\texttt{.S3PrimitiveGenerics} is a character vector listing the primitives which are internal generic and not \texttt{group generic}. Currently \texttt{as.vector, cbind, rbind} and \texttt{unlist} are the internal non-primitive functions which are internally generic.

For efficiency, internal dispatch only occurs on \texttt{objects}, that is those for which \texttt{is.object} returns true.

\texttt{methods} for the methods which are available.

---

\textbf{invisible} \textit{Change the Print Mode to Invisible}

\textbf{Description}

Return a (temporarily) invisible copy of an object.

\textbf{Usage}

\texttt{invisible(x)}

\textbf{Arguments}

\texttt{x} an arbitrary \texttt{R} object.

\textbf{Details}

This function can be useful when it is desired to have functions return values which can be assigned, but which do not print when they are not assigned.

This is a \texttt{primitive} function.

\textbf{References}

\textbf{See Also}

\texttt{withVisible, return, function}. 
Examples

# These functions both return their argument
f1 <- function(x) x
f2 <- function(x) invisible(x)
f1(1) # prints
f2(1) # does not

is.finite

Finite, Infinite and NaN Numbers

Description

is.finite and is.infinite return a vector of the same length as x, indicating which elements are finite (not infinite and not missing) or infinite.

Inf and -Inf are positive and negative infinity whereas NaN means ‘Not a Number’. (These apply to numeric values and real and imaginary parts of complex values but not to values of integer vectors.) Inf and NaN are reserved words in the R language.

Usage

is.finite(x)
is.infinite(x)
is.nan(x)

Inf
NaN

Arguments

x

R object to be tested: the default methods handle atomic vectors.

Details

is.finite returns a vector of the same length as x the jth element of which is TRUE if x[j] is finite (i.e., it is not one of the values NA, NaN, Inf or -Inf) and FALSE otherwise. Complex numbers are finite if both the real and imaginary parts are.

is.infinite returns a vector of the same length as x the jth element of which is TRUE if x[j] is infinite (i.e., equal to one of Inf or -Inf) and FALSE otherwise. This will be false unless x is numeric or complex. Complex numbers are infinite if either the real or the imaginary part is.

is.nan tests if a numeric value is NaN. Do not test equality to NaN, or even use identical, since systems typically have many different NaN values. One of these is used for the numeric missing value NA, and is.nan is false for that value. A complex number is regarded as NaN if either the real or imaginary part is NaN but not NA. All elements of logical, integer and raw vectors are considered not to be NaN.

All three functions accept NULL as input and return a length zero result. The default methods accept character and raw vectors, and return FALSE for all entries. Prior to R version 2.14.0 they accepted all input, returning FALSE for most non-numeric values; cases which are not atomic vectors are now signalled as errors.

All three functions are generic: you can write methods to handle specific classes of objects, see InternalMethods.
Value
A logical vector of the same length as x: dims, dimnames and names attributes are preserved.

Note
In R, basically all mathematical functions (including basic Arithmetic), are supposed to work properly with +/-Inf and NaN as input or output.
The basic rule should be that calls and relations with Infs really are statements with a proper mathematical limit.
Computations involving NaN will return NaN or perhaps NA: which of those two is not guaranteed and may depend on the R platform (since compilers may re-order computations).

References

Also available at https://docs.oracle.com/cd/E19957-01/806-3568/ncg_goldberg.html.
The C99 function isfinite is used for is.finite.

See Also
NA, 'Not Available' which is not a number as well, however usually used for missing values and applies to many modes, not just numeric and complex.
Arithmetic, double.

Examples
pi / 0 ## = Inf a non-zero number divided by zero creates infinity
0 / 0 ## = NaN

1/0 + 1/0 # Inf
1/0 - 1/0 # NaN

stopifnot(
  1/0 == Inf,
  1/Inf == 0
)
sin(Inf)
cos(Inf)
tan(Inf)
is.function

Is an Object of Type (Primitive) Function?

Description
Checks whether its argument is a (primitive) function.

Usage

is.function(x)

is.primitive(x)

Arguments

x an R object.

Details

is.primitive(x) tests if x is a primitive function, i.e, if typeof(x) is either "builtin" or "special".

Value

TRUE if x is a (primitive) function, and FALSE otherwise.

Examples

is.function(1) # FALSE
is.function(is.primitive) # TRUE: it is a function, but ..
is.primitive(is.primitive) # FALSE: it's not a primitive one, whereas
is.primitive(is.function) # TRUE: that one *is*

is.language

Is an Object a Language Object?

Description

is.language returns TRUE if x is a variable name, a call, or an expression.

Usage

is.language(x)

Arguments

x object to be tested.
is.object

Note

A name is also known as ‘symbol’, from its type (typeof), see is.symbol.

If typeof(x) == "language", then is.language(x) is always true, but the reverse does not hold as expressions or names y also fulfill is.language(y), see the examples.

This is a primitive function.

References

Examples

ll <- list(a = expression(x^2 - 2*x + 1), b = as.name("Jim"),
          c = as.expression(exp(1)), d = call("sin", pi))
sapply(ll, typeof)
sapply(ll, mode)
stopifnot(sapply(ll, is.language))

is.object        Is an Object 'internally classed'?

Description

A function rather for internal use. It returns TRUE if the object x has the R internal OBJECT bit set, and FALSE otherwise. The OBJECT bit is set when a "class" attribute is added and removed when that attribute is removed, so this is a very efficient way to check if an object has a class attribute. (S4 objects always should.)

Usage

is.object(x)

Arguments

x  object to be tested.

Note

This is a primitive function.

See Also

class, and methods.

isS4.

Examples

is.object(1)  # FALSE
is.object(as.factor(1:3))  # TRUE
**Description**

Test if running under R.

**Usage**

```r
is.R()
```

**Details**

The function has been written such as to correctly run in all versions of R, S and S-PLUS. In order for code to be runnable in both R and S dialects previous to S-PLUS 8.0, your code must either define is.R or use it as

```r
if(exists("is.R") && is.function(is.R) && is.R()) {
  ## R-specific code
} else {
  ## S-version of code
}
```

**Value**

is.R returns TRUE if we are using R and FALSE otherwise.

**See Also**

`R.version`, `system`.

**Examples**

```r
x <- stats::runif(20); small <- x < 0.4
## In the early years of R, 'which()' only existed in R:
if(is.R()) which(small) else seq(along = small)[small]
```

---

**is.recursive**

*Is an Object Atomic or Recursive?*

**Description**

`is.atomic` returns TRUE if x is of an atomic type (or NULL) and FALSE otherwise.

`is.recursive` returns TRUE if x has a recursive (list-like) structure and FALSE otherwise.

**Usage**

```r
is.atomic(x)
is.recursive(x)
```
is.single

Description

is.single reports an error. There are no single precision values in R.

Usage

is.single(x)

Arguments

x object to be tested.
is.unsorted

Test if an Object is Not Sorted

Description

Test if an object is not sorted (in increasing order), without the cost of sorting it.

Usage

is.unsorted(x, na.rm = FALSE, strictly = FALSE)

Arguments

x an R object with a class or a numeric, complex, character, logical or raw vector.
na.rm logical. Should missing values be removed before checking?
strictly logical indicating if the check should be for strictly increasing values.

Details

is.unsorted is generic: you can write methods to handle specific classes of objects, see Internal-Methods.

Value

A length-one logical value. All objects of length 0 or 1 are sorted. Otherwise, the result will be NA except for atomic vectors and objects with an S3 class (where the \(\geq\) or \(>\) method is used to compare \(x[i]\) with \(x[i-1]\) for \(i\) in \(2:\text{length}(x)\)) or with an S4 class where you have to provide a method for is.unsorted().

Note

This function is designed for objects with one-dimensional indices, as described above. Data frames, matrices and other arrays may give surprising results.

See Also

sort, order.

References

Date-time Conversion Functions from Numeric Representations

Description

Convenience wrappers to create date-times from numeric representations.

Usage

ISOdatetime(year, month, day, hour, min, sec, tz = "")
ISOdate(year, month, day, hour = 12, min = 0, sec = 0, tz = "GMT")

Arguments

- year, month, day
  numerical values to specify a day.
- hour, min, sec
  numerical values for a time within a day. Fractional seconds are allowed.
- tz
  A time zone specification to be used for the conversion. "" is the current time zone and "GMT" is UTC. Invalid values are most commonly treated as UTC, on some platforms with a warning.

Details

ISOdatetime and ISOdate are convenience wrappers for `strptime` that differ only in their defaults and that ISOdate sets UTC as the time zone. For dates without times it would normally be better to use the "Date" class.

The main arguments will be recycled using the usual recycling rules.

Because these make use of `strptime`, only years in the range 0:9999 are accepted.

Value

An object of class "POSIXct".

See Also

DateTimeClasses for details of the date-time classes; `strptime` for conversions from character strings.

Test for an S4 object

isS4

Description

Tests whether the object is an instance of an S4 class.
Usage

isS4(object)

asS4(object, flag = TRUE, complete = TRUE)
asS3(object, flag = TRUE, complete = TRUE)

Arguments

object       Any R object.
flag         Optional, logical: indicate direction of conversion.
complete     Optional, logical: whether conversion to S3 is completed. Not usually needed, but see the details section.

Details

Note that isS4 does not rely on the methods package, so in particular it can be used to detect the need to require that package.

asS3 uses the value of complete to control whether an attempt is made to transform object into a valid object of the implied S3 class. If complete is TRUE, then an object from an S4 class extending an S3 class will be transformed into an S3 object with the corresponding S3 class (see S3Part). This includes classes extending the pseudo-classes array and matrix: such objects will have their class attribute set to NULL.

isS4 is primitive.

Value

isS4 always returns TRUE or FALSE according to whether the internal flag marking an S4 object has been turned on for this object.

asS4 and asS3 will turn this flag on or off, and asS3 will set the class from the objects .S3Class slot if one exists. Note that asS3 will not turn the object into an S3 object unless there is a valid conversion; that is, an object of type other than "S4" for which the S4 object is an extension, unless argument complete is FALSE.

See Also

is.object for a more general test; Introduction for general information on S4; Classes_Details for more on S4 class definitions.

Examples

isS4(pi)  # FALSE
isS4(getClass("MethodDefinition"))  # TRUE
isSymmetric  Test if a Matrix or other Object is Symmetric (Hermitian)

Description

Generic function to test if object is symmetric or not. Currently only a matrix method is implemented, where a complex matrix Z must be “Hermitian” for isSymmetric(Z) to be true.

Usage

isSymmetric(object, ...)  
## S3 method for class 'matrix'
isSymmetric(object, tol = 100 * .Machine$double.eps,
tol1 = 8 * tol, ...)

Arguments

object  any R object; a matrix for the matrix method.
tol  numeric scalar $\geq 0$. Smaller differences are not considered, see all.equal.numeric.
tol1  numeric scalar $\geq 0$. isSymmetric.matrix() ‘pre-tests’ the first and last few rows for fast detection of ‘obviously’ asymmetric cases with this tolerance. Setting it to length zero will skip the pre-tests.
...
  further arguments passed to methods; the matrix method passes these to all.equal. If the row and column names of object are allowed to differ for the symmetry check do use check.attributes = FALSE!

Details

The matrix method is used inside eigen by default to test symmetry of matrices up to rounding error, using all.equal. It might not be appropriate in all situations.

Note that a matrix m is only symmetric if its rownames and colnames are identical. Consider using unname(m).

Value

logical indicating if object is symmetric or not.

See Also

eigen which calls isSymmetric when its symmetric argument is missing.

Examples

isSymmetric(D3 <- diag(3)) # -> TRUE

D3[2, 1] <- 1e-100
D3
isSymmetric(D3) # TRUE
isSymmetric(D3, tol = 0) # FALSE for zero-tolerance
### Complex Matrices - Hermitian or not

```r
Z <- sqrt(matrix(-1:2 + 0i, 2)); Z <- t(Conj(Z)) %% Z
Z
isSymmetric(Z) # TRUE
isSymmetric(Z + 1) # TRUE
isSymmetric(Z + 1i) # FALSE -- a Hermitian matrix has a *real* diagonal
```

```r
colnames(D3) <- c("X", "Y", "Z")
isSymmetric(D3) # FALSE (as row and column names differ)
isSymmetric(D3, check.attributes=FALSE) # TRUE (as names are not checked)
```

---

## jitter 'Jitter' (Add Noise) to Numbers

### Description

Add a small amount of noise to a numeric vector.

### Usage

```r
jitter(x, factor = 1, amount = NULL)
```

### Arguments

- `x` numeric vector to which `jitter` should be added.
- `factor` numeric.
- `amount` numeric; if positive, used as `amount` (see below), otherwise, if = 0 the default is `factor * z/50`. Default (NULL): `factor * d/5` where `d` is the smallest difference between `x` values.

### Details

The result, say `r`, is `r <- x + runif(n,-a,a)` where `n <- length(x)` and `a` is the amount argument (if specified). Let `z <- max(x) - min(x)` (assuming the usual case). The amount `a` to be added is either provided as `positive` argument `amount` or otherwise computed from `z`, as follows:

- If `amount == 0`, we set `a <- factor * z/50` (same as S).
- If `amount` is NULL (default), we set `a <- factor * d/5` where `d` is the smallest difference between adjacent unique (apart from fuzz) `x` values.

### Value

`jitter(x,...)` returns a numeric of the same length as `x`, but with an amount of noise added in order to break ties.

rug which you may want to combine with jitter.

Examples

round(jitter(c(rep(1, 3), rep(1.2, 4), rep(3, 3))), 3)
## These two 'fail' with S-plus 3.x:
jitter(rep(0, 7))
jitter(rep(10000, 5))

kappa

*Compute or Estimate the Condition Number of a Matrix*

Description

The condition number of a regular (square) matrix is the product of the norm of the matrix and the norm of its inverse (or pseudo-inverse), and hence depends on the kind of matrix-norm.

kappa() computes by default (an estimate of) the 2-norm condition number of a matrix or of the R matrix of a QR decomposition, perhaps of a linear fit. The 2-norm condition number can be shown to be the ratio of the largest to the smallest non-zero singular value of the matrix.

rcond() computes an approximation of the reciprocal condition number, see the details.

Usage

kappa(z, ...)
## Default S3 method:
kappa(z, exact = FALSE, 
    norm = NULL, method = c("qr", "direct"), ...)
## S3 method for class ‘lm’
kappa(z, ...)
## S3 method for class ‘qr’
kappa(z, ...)

.kappa_tri(z, exact = FALSE, LINPACK = TRUE, norm = NULL, ...)

rcond(x, norm = c("O","I","1"), triangular = FALSE, ...)

Arguments

z, x  A matrix or a the result of qr or a fit from a class inheriting from "lm".
exact  logical. Should the result be exact?
norm  character string, specifying the matrix norm with respect to which the condition number is to be computed, see also norm. For rcond, the default is "O", meaning the One- or 1-norm. The (currently only) other possible value is "I" for the infinity norm.
method a partially matched character string specifying the method to be used; "qr" is the default for back-compatibility, mainly.

triangular logical. If true, the matrix used is just the lower triangular part of z.

LINPACK logical. If true and z is not complex, the LINPACK routine dtrco() is called; otherwise the relevant LAPACK routine is.

... further arguments passed to or from other methods; for kappa.*, notably LINPACK when norm is not "2".

Details

For kappa(), if exact = FALSE (the default) the 2-norm condition number is estimated by a cheap approximation. However, the exact calculation (via svd) is also likely to be quick enough.

Note that the 1- and Inf-norm condition numbers are much faster to calculate, and rcond() computes these reciprocal condition numbers, also for complex matrices, using standard LAPACK routines.

kappa and rcond are different interfaces to partly identical functionality.

Unsuccessful results from the underlying LAPACK code will result in an error giving a positive error code: these can only be interpreted by detailed study of the FORTRAN code.

Value

The condition number, kappa, or an approximation if exact = FALSE.

Author(s)

The design was inspired by (but differs considerably from) the S function of the same name described in Chambers (1992).

## `kronecker`  

### Kronecker Products on Arrays

**Description**

Computes the generalised kronecker product of two arrays, `X` and `Y`.

**Usage**

```r
kronecker(X, Y, FUN = "+", make.dimnames = FALSE, ...)
X %x% Y
```

**Arguments**

- `X` : A vector or array.
- `Y` : A vector or array.
- `FUN` : a function; it may be a quoted string.
- `make.dimnames` : Provide dimnames that are the product of the dimnames of `X` and `Y`.
- `...` : optional arguments to be passed to `FUN`.

**Details**

If `X` and `Y` do not have the same number of dimensions, the smaller array is padded with dimensions of size one. The returned array comprises submatrices constructed by taking `X` one term at a time and expanding that term as `FUN(x,Y,...)`.

`%x%` is an alias for `kronecker` (where `FUN` is hardwired to "+").

**Value**

An array `A` with dimensions `dim(X) * dim(Y)`.

bill <- outer(bill, c("cat" = 3, "dog" = 4))
kronencker(fred, bill, make.dimnames = TRUE)
labels

\textit{Find Labels from Object}

\textbf{Description}

Find a suitable set of labels from an object for use in printing or plotting, for example. A generic function.

\textbf{Usage}

\begin{verbatim}
labels(object, ...)
\end{verbatim}

\textbf{Arguments}

- \texttt{object} \hspace{1cm} Any R object: the function is generic.
- \texttt{...} \hspace{1cm} further arguments passed to or from other methods.

\textbf{Value}

A character vector or list of such vectors. For a vector the results is the names or seq_along(x) and for a data frame or array it is the dimnames (with \texttt{NULL} expanded to seq_len(d[i])).

\textbf{References}

\begin{verbatim}
\end{verbatim}

\textbf{lapply}

\textit{Apply a Function over a List or Vector}

\textbf{Description}

\texttt{lapply} returns a list of the same length as \texttt{X}, each element of which is the result of applying \texttt{FUN} to the corresponding element of \texttt{X}.

\texttt{sapply} is a user-friendly version and wrapper of \texttt{lapply} by default returning a vector, matrix or, if \texttt{simplify = "array"}, an array if appropriate, by applying \texttt{simplify2array()}. \texttt{sapply(x,f,simplify = FALSE,USE.NAMES = FALSE)} is the same as \texttt{lapply(x,f)}.

\texttt{vapply} is similar to \texttt{sapply}, but has a pre-specified type of return value, so it can be safer (and sometimes faster) to use.

\texttt{replicate} is a wrapper for the common use of \texttt{sapply} for repeated evaluation of an expression (which will usually involve random number generation).

\texttt{\texttt{simplify2array()}} is the utility called from \texttt{sapply()} when \texttt{simplify} is not false and is similarly called from \texttt{\texttt{mapply()}}.
lapply

Usage

lapply(X, FUN, ...)  
sapply(X, FUN, ..., simplify = TRUE, USE.NAMES = TRUE)  
vapply(X, FUN, FUN.VALUE, ..., USE.NAMES = TRUE)  
replicate(n, expr, simplify = "array")  
simplify2array(x, higher = TRUE)

Arguments

X a vector (atomic or list) or an expression object. Other objects (including classed objects) will be coerced by base::as.list.

FUN the function to be applied to each element of X: see ‘Details’. In the case of functions like +, %*%, the function name must be backquoted or quoted.

... optional arguments to FUN.

simplify logical or character string: should the result be simplified to a vector, matrix or higher dimensional array if possible? For sapply it must be named and not abbreviated. The default value, TRUE, returns a vector or matrix if appropriate, whereas if simplify = "array" the result may be an array of “rank” (=length(dim(.))) one higher than the result of FUN(X[[i]]).

USE.NAMES logical; if TRUE and if X is character, use X as names for the result unless it had names already. Since this argument follows ... its name cannot be abbreviated.

FUN.VALUE a (generalized) vector; a template for the return value from FUN. See ‘Details’.

n integer: the number of replications.

expr the expression (a language object, usually a call) to evaluate repeatedly.

x a list, typically returned from lapply().

higher logical; if true, simplify2array() will produce a (“higher rank”) array when appropriate, whereas higher = FALSE would return a matrix (or vector) only. These two cases correspond to sapply(\+, simplify = "array") or simplify = TRUE, respectively.

Details

FUN is found by a call to match.fun and typically is specified as a function or a symbol (e.g., a backquoted name) or a character string specifying a function to be searched for from the environment of the call to lapply.

Function FUN must be able to accept as input any of the elements of X. If the latter is an atomic vector, FUN will always be passed a length-one vector of the same type as X.

Arguments in ... cannot have the same name as any of the other arguments, and care may be needed to avoid partial matching to FUN. In general-purpose code it is good practice to name the first two arguments X and FUN if ... is passed through: this both avoids partial matching to FUN and ensures that a sensible error message is given if arguments named X or FUN are passed through . . . . Simplification in sapply is only attempted if X has length greater than zero and if the return values from all elements of X are all of the same (positive) length. If the common length is one the result is a vector, and if greater than one is a matrix with a column corresponding to each element of X.
Simplification is always done in \texttt{vapply}. This function checks that all values of \texttt{FUN} are compatible with the \texttt{FUN.VALUE}, in that they must have the same length and type. (Types may be promoted to a higher type within the ordering logical < integer < double < complex, but not demoted.)

Users of S4 classes should pass a list to \texttt{lapply} and \texttt{vapply}: the internal coercion is done by the \texttt{as.list} in the base namespace and not one defined by a user (e.g., by setting S4 methods on the base function).

\textbf{Value}

For \texttt{lapply}, \texttt{sapply(simplify = FALSE)} and \texttt{replicate(simplify = FALSE)}, a list.

For \texttt{sapply(simplify = TRUE)} and \texttt{replicate(simplify = TRUE)}: if \texttt{X} has length zero or \texttt{n = 0}, an empty list. Otherwise an atomic vector or matrix or list of the same length as \texttt{X} (of length \texttt{n} for \texttt{replicate}). If simplification occurs, the output type is determined from the highest type of the return values in the hierarchy \texttt{NULL < raw < logical < integer < double < complex < character < list < expression}, after coercion of \texttt{pairlists} to lists.

\texttt{vapply} returns a vector or array of type matching the \texttt{FUN.VALUE}. If \texttt{length(FUN.VALUE) == 1} a vector of the same length as \texttt{X} is returned, otherwise an array. If \texttt{FUN.VALUE} is not an \texttt{array}, the result is a matrix with \texttt{length(FUN.VALUE)} rows and \texttt{length(X)} columns, otherwise an array \texttt{a} with \texttt{dim(a) == c(dim(FUN.VALUE),length(X))}.

The (Dim)names of the array value are taken from the \texttt{FUN.VALUE} if it is named, otherwise from the result of the first function call. Column names of the matrix or more generally the names of the last dimension of the array value or names of the vector value are set from \texttt{X} as in \texttt{sapply}.

\textbf{Note}

\texttt{sapply(*,simplify = FALSE,USE.NAMES = FALSE)} is equivalent to \texttt{lapply(*)}.

For historical reasons, the calls created by \texttt{lapply} are unevaluated, and code has been written (e.g., \texttt{bquote}) that relies on this. This means that the recorded call is always of the form \texttt{FUN(X[[i]],...)}, with \texttt{i} replaced by the current (integer or double) index. This is not normally a problem, but it can be if \texttt{FUN} uses \texttt{sys.call} or \texttt{match.call} or if it is a primitive function that makes use of the call. This means that it is often safer to call primitive functions with a wrapper, so that e.g. \texttt{lapply(ll,function(x) is.numeric(x))} is required to ensure that method dispatch for \texttt{is.numeric} occurs correctly.

If \texttt{expr} is a function call, be aware of assumptions about where it is evaluated, and in particular what \texttt{...} might refer to. You can pass additional named arguments to a function call as additional named arguments to \texttt{replicate}: see ‘Examples’.

\textbf{References}

\textbf{See Also}

\texttt{apply}, \texttt{tapply}, \texttt{mapply} for applying a function to multiple arguments, and \texttt{rapply} for a recursive version of \texttt{lapply}(), \texttt{eapply} for applying a function to each entry in an \texttt{environment}.

\textbf{Examples}

\begin{verbatim}
require(stats); require(graphics)

x <- list(a = 1:10, beta = exp(-3:3), logic = c(TRUE,FALSE,FALSE,TRUE))
\end{verbatim}
Last.value

# compute the list mean for each list element
lapply(x, mean)
# median and quartiles for each list element
lapply(x, quantile, probs = 1:3/4)
sapply(x, quantile)
i39 <- sapply(3:9, seq) # list of vectors
sapply(i39, fivenum)
vapply(i39, fivenum,
c(Min. = 0, "1st Qu." = 0, Median = 0, "3rd Qu." = 0, Max. = 0))

## sapply(*, "array") -- artificial example
(v <- structure(10*(5:8), names = LETTERS[1:4]))
f2 <- function(x, y) outer(rep(x, length.out = 3), y)
(a2 <- sapply(v, f2, y = 2*(1:5), simplify = "array"))
a.2 <- vapply(v, f2, outer(1:3, 1:5), y = 2*(1:5))
stopifnot(dim(a2) == c(3,5,4), all.equal(a2, a.2),
        identical(dimnames(a2), list(NULL,NULL,LETTERS[1:4])))

hist(replicate(100, mean(rexp(10))))

## use of replicate() with parameters:
foo <- function(x = 1, y = 2) c(x, y)
# does not work: bar <- function(n, ...) replicate(n, foo(...))
bar <- function(n, x) replicate(n, foo(x = x))
bar(5, x = 3)

---

### Last.value

**Value of Last Evaluated Expression**

#### Description

The value of the internal evaluation of a top-level \texttt{R} expression is always assigned to \texttt{.Last.value} (in package:base) before further processing (e.g., printing).

#### Usage

\texttt{.Last.value}

#### Details

The value of a top-level assignment \texttt{is} put in \texttt{.Last.value}, unlike \texttt{S}.

Do not assign to \texttt{.Last.value} in the workspace, because this will always mask the object of the same name in package:base.

#### See Also

\texttt{eval}
La_library

Examples

```r
## These will not work correctly from example(),
## but they will in make check or if pasted in,
## as example() does not run them at the top level
gamma(1:15)  # think of some intensive calculation...
fac14 <- .Last.value # keep them

library("splines") # returns invisibly
.Last.value       # shows what library(.) above returned
```

La_library

LAPACK Library

Description

Report the name of the shared object file with LAPACK implementation in use.

Usage

```r
La_library()
```

Value

A character vector of length one ("" when the name is not known). The value can be used as an indication of which LAPACK implementation is in use. Typically, the R version of LAPACK will appear as `libRlapack.so` (\`libRlapack.dylib\`), depending on how R was built. Note that `libRlapack.so` (\`libRlapack.dylib\`) may also be shown for an external LAPACK implementation that had been copied, hard-linked or renamed by the system administrator. Otherwise, the shared object file will be given and its path/name may indicate the vendor/version. The detection does not work on Windows.

See Also

`extSoftVersion` for versions of other third-party software including BLAS.

`La_version` for the version of LAPACK in use.

Examples

```r
La_library()
```
La_version

LAPACK Version

Description
Report the version of LAPACK in use.

Usage
La_version()

Value
A character vector of length one.

See Also
extSoftVersion for versions of other third-party software.
La_library for binary/executable file with LAPACK in use.

Examples
La_version()

length

Length of an Object

Description
Get or set the length of vectors (including lists) and factors, and of any other R object for which a method has been defined.

Usage
length(x)
length(x) <- value

Arguments
x an R object. For replacement, a vector or factor.
value a non-negative integer or double (which will be rounded down).

Details
Both functions are generic: you can write methods to handle specific classes of objects, see InternalMethods. length<- has a "factor" method.

The replacement form can be used to reset the length of a vector. If a vector is shortened, extra values are discarded and when a vector is lengthened, it is padded out to its new length with NAs (nul for raw vectors).

Both are primitive functions.
Value

The default method for `length` currently returns a non-negative `integer` of length 1, except for vectors of more than $2^{31} - 1$ elements, when it returns a double.

For vectors (including lists) and factors the length is the number of elements. For an environment it is the number of objects in the environment, and `NULL` has length 0. For expressions and pairlists (including `language objects` and `dotlists`) it is the length of the pairlist chain. All other objects (including functions) have length one: note that for functions this differs from S.

The replacement form removes all the attributes of `x` except its names, which are adjusted (and if necessary extended by "").

Warning

Package authors have written methods that return a result of length other than one (Formula) and that return a vector of type `double` (Matrix), even with non-integer values (earlier versions of sets). Where a single double value is returned that can be represented as an integer it is returned as a length-one integer vector.

References

See Also

`nchar` for counting the number of characters in character vectors, `lengths` for getting the length of every element in a list.

Examples

```r
length(diag(4))  # = 16 (4 x 4)
length(options()) # 12 or more
length(y ~ x1 + x2 + x3) # 3
length(expression(x, {y <- x^2; y+2}, x^y)) # 3

## from example(warpbreaks)
require(stats)
fm1 <- lm(breaks ~ wool * tension, data = warpbreaks)
length(fm1$call) # 3, lm() and two arguments.
length(formula(fm1)) # 3, ~ lhs rhs
```

`lengths` Lengths of List or Vector Elements

Description

Get the length of each element of a `list` or atomic vector (`is.atomic`) as an integer or numeric vector.

Usage

`lengths(x, use.names = TRUE)`
Arguments

- **x**: a **list**, list-like such as an **expression** or an atomic vector (for which the result is trivial).
- **use.names**: logical indicating if the result should inherit the names from `x`.

Details

This function loops over `x` and returns a compatible vector containing the length of each element in `x`. Effectively, `length(x[[i]])` is called for all `i`, so any methods on length are considered.

`lengths` is generic: you can write methods to handle specific classes of objects, see `InternalMethods`.

Value

A non-negative **integer** of length `length(x)`, except when any element has a length of more than $2^{31} - 1$ elements, when it returns a double vector. When `use.names` is true, the names are taken from the names on `x`, if any.

Note

One raison d’être of `lengths(x)` is its use as a more efficient version of `sapply(x, length)` and similar `*apply` calls to `length`. This is the reason why `x` may be an atomic vector, even though `lengths(x)` is trivial in that case.

See Also

- **length** for getting the length of any R object.

Examples

```r
require(stats)
## summarize by month
l <- split(airquality$Ozone, airquality$Month)
avgOz <- lapply(l, mean, na.rm=TRUE)
## merge result
airquality$avgOz <- rep(unlist(avgOz, use.names=FALSE), lengths(l))
## but this is safer and cleaner, but can be slower
airquality$avgOz <- unsplit(avgOz, airquality$Month)
## should always be true, except when a length does not fit in 32 bits
stopifnot(identical(lengths(l), vapply(l, length, integer(1L))))
## empty lists are not a problem
x <- list()
stopifnot(identical(lengths(x), integer()))
## nor are "list-like" expressions:
lengths(expression(u, v, 1:0:9))
## and we should dispatch to length methods
f <- c(rep(1, 3), rep(2, 6), 3)
dates <- split(as.POSIXlt(Sys.time() + 1:10), f)
stopifnot(identical(lengths(dates), vapply(dates, length, integer(1L))))
```
levels  

Levels Attributes

Description

levels provides access to the levels attribute of a variable. The first form returns the value of the levels of its argument and the second sets the attribute.

Usage

```r
levels(x)
levels(x) <- value
```

Arguments

- `x`: an object, for example a factor.
- `value`: A valid value for `levels(x)`. For the default method, NULL or a character vector. For the `factor` method, a vector of character strings with length at least the number of levels of `x`, or a named list specifying how to rename the levels.

Details

Both the extractor and replacement forms are generic and new methods can be written for them. The most important method for the replacement function is that for `factor`.

For the factor replacement method, a NA in `value` causes that level to be removed from the levels and the elements formerly with that level to be replaced by NA.

Note that for a factor, replacing the levels via `levels(x) <- value` is not the same as (and is preferred to) `attr(x, "levels") <- value`.

The replacement function is primitive.

`nlevels`, `relevel`, `reorder`.

Examples

```r
## assign individual levels
x <- gl(2, 4, 8)
levels(x)[1] <- "low"
levels(x)[2] <- "high"
x

## or as a group
y <- gl(2, 4, 8)
levels(y) <- c("low", "high")
y
```
libcurlVersion

## combine some levels
z <- gl(3, 2, 12, labels = c("apple", "salad", "orange"))
z
levels(z) <- c("fruit", "veg", "fruit")
z

## same, using a named list
z <- gl(3, 2, 12, labels = c("apple", "salad", "orange"))
z
levels(z) <- list("fruit" = c("apple", "orange"),
               "veg"   = "salad")
z

## we can add levels this way:
f <- factor(c("a", "b"))
levels(f) <- c("c", "a", "b")
f

f <- factor(c("a", "b"))
levels(f) <- list(C = "C", A = "a", B = "b")
f

### libcurlVersion

#### Report Version of libcurl

**Description**

Report version of libcurl in use.

**Usage**

libcurlVersion()

**Value**

A character string, with value the **libcurl** version in use or "" if none is. If **libcurl** is available, has attributes

- **ssl_version** A character string naming the SSL/TLS implementation and version, possibly "none". It is intended for the version of OpenSSL used, but not all implementations of **libcurl** use OpenSSL — for example macOS reports "SecureTranspart", its wrapper for SSL/TLS.

- **libssh_version** A character string naming the **libssh** version, which may or may not be available (it is used for e.g. scp and sftp protocols). Where present, something like "libssh2/1.5.0".

- **protocols** A character vector of the names of supported protocols, also known as ‘schemes’ when part of a URL.

**Warning**

In late 2017 a **libcurl** installation was seen divided into two libraries, **libcurl** and **libcurl-feature**, and the first had been updated but not the second. As the compiled function recording the version was in the latter, the version reported by **libcurlVersion** was misleading.
libPaths

See Also

extSoftVersion for versions of other third-party software.
curlGetHeaders, download.file and url for functions which (optionally) use libcurl.
https://curl.haxx.se/docs/sslcerts.html and https://curl.haxx.se/docs/ssl-compared.html for more details on SSL versions (the current standard being known as TLS). Normally libcurl used with R uses SecureTransport on macOS, OpenSSL on Windows and GnuTLS, NSS or OpenSSL on Unix-alikes. (At the time of writing Debian-based Linuxen use GnuTLS and RedHat-based ones use NSS, but it has been announced that Fedora 27 will switch to OpenSSL.)

Examples

libcurlVersion()

libPaths

Search Paths for Packages

Description

.libPaths gets/sets the library trees within which packages are looked for.

Usage

.libPaths(new)

.Library
.Library.site

Arguments

new a character vector with the locations of R library trees. Tilde expansion (path.expand) is done, and if any element contains one of *?[], globbing is done where supported by the platform: see Sys.glob.

Details

.Library is a character string giving the location of the default library, the 'library' subdirectory of R_HOME.
.Library.site is a (possibly empty) character vector giving the locations of the site libraries, by default the 'site-library' subdirectory of R_HOME (which may not exist).
.libPaths is used for getting or setting the library trees that R knows about (and hence uses when looking for packages). If called with argument new, the library search path is set to the existing directories in unique(c(new,.Library.site,.Library)) and this is returned. If given no argument, a character vector with the currently active library trees is returned.

How paths new with a trailing slash are treated is OS-dependent. On a POSIX filesystem existing directories can usually be specified with a trailing slash: on Windows filepaths with a trailing slash (or backslash) are invalid and so will never be added to the library search path.

The library search path is initialized at startup from the environment variable R_LIBS (which should be a colon-separated list of directories at which R library trees are rooted) followed by those in environment variable R_LIBS_USER. Only directories which exist at the time will be included.
By default `R_LIBS` is unset, and `R_LIBS_USER` is set to directory 
`R/R.version$platform/library/x.y` of the home directory (or `Library/R/x.y/library` 
for CRAN macOS builds), for R\_x.y.z.

`.Library.site` can be set via the environment variable `R_LIBS_SITE` (as a non-empty colon-separated list of library trees).

Both `R_LIBS_USER` and `R_LIBS_SITE` feature possible expansion of specifiers for R version specific information as part of the startup process. The possible conversion specifiers all start with a `%` and are followed by a single letter (use `%%` to obtain `%`), with currently available conversion specifications as follows:

`%V` R version number including the patchlevel (e.g., `2.5.0`).
`%v` R version number excluding the patchlevel (e.g., `2.5`).
`%p` the platform for which R was built, the value of `R.version$platform`. 
`%o` the underlying operating system, the value of `R.version$os`. 
`%a` the architecture (CPU) R was built on/for, the value of `R.version$arch`. 

(See `version` for details on R version information.)

Function `.libPaths` always uses the values of `.Library` and `.Library.site` in the base namespace. `.Library.site` can be set by the site in `Rprofile.site`, which should be followed by a call to `.libPaths(.libPaths())` to make use of the updated value.

For consistency, the paths are always normalized by `normalizePath(winslash = "/")`.

**Value**

A character vector of file paths.

**References**

**See Also**

`library`

**Examples**

`.libPaths()` # all library trees R knows about

---

**library**

*Loading/Attaching and Listing of Packages*

**Description**

`library` and `require` load and attach add-on packages.
Usage

library(package, help, pos = 2, lib.loc = NULL,
        character.only = FALSE, logical.return = FALSE,
        warn.conflicts, quietly = FALSE,
        verbose = getOption("verbose"),
        mask.ok, exclude, include.only,
        attach.required = missing(include.only))

require(package, lib.loc = NULL, quietly = FALSE,
        warn.conflicts,
        character.only = FALSE,
        mask.ok, exclude, include.only,
        attach.required = missing(include.only))

conflictRules(pkg, mask.ok = NULL, exclude = NULL)

Arguments

package, help  the name of a package, given as a name or literal character string, or a character string, depending on whether character.only is FALSE (default) or TRUE.
pos  the position on the search list at which to attach the loaded namespace. Can also be the name of a position on the current search list as given by search().
lib.loc  a character vector describing the location of R library trees to search through, or NULL. The default value of NULL corresponds to all libraries currently known to .libPaths(). Non-existent library trees are silently ignored.
character.only  a logical indicating whether package or help can be assumed to be character strings.
logical.return  logical. If it is TRUE, FALSE or TRUE is returned to indicate success.
warn.conflicts  logical. If TRUE, warnings are printed about conflicts from attaching the new package. A conflict is a function masking a function, or a non-function masking a non-function. The default is TRUE unless specified as FALSE in the conflicts.policy option.
verbose  a logical. If TRUE, additional diagnostics are printed.
quietly  a logical. If TRUE, no message confirming package attaching is printed, and most often, no errors/warnings are printed if package attaching fails.
pkg  character string naming a package.
mask.ok  character vector of names of objects that can mask objects on the search path without signaling an error when strict conflict checking is enabled
exclude.include.only  character vector of names of objects to exclude or include in the attached frame. Only one of these arguments may be used in a call to library or require.
attach.required  logical specifying whether required packages listed in the Depends clause of the DESCRIPTION file should be attached automatically.

Details

library(package) and require(package) both load the namespace of the package with name package and attach it on the search list. require is designed for use inside other functions; it returns
FALSE and gives a warning (rather than an error as `library()` does by default) if the package does not exist. Both functions check and update the list of currently attached packages and do not reload a namespace which is already loaded. (If you want to reload such a package, call `detach(unload = TRUE)` or `unloadNamespace` first.) If you want to load a package without attaching it on the search list, see `requireNamespace`.

To suppress messages during the loading of packages use `suppressPackageStartupMessages`: this will suppress all messages from R itself but not necessarily all those from package authors.

If `library` is called with no package or help argument, it lists all available packages in the libraries specified by `lib.loc`, and returns the corresponding information in an object of class "libraryIQR". (The structure of this class may change in future versions.) Use `.packages(all = TRUE)` to obtain just the names of all available packages, and `installed.packages()` for even more information.

`library(help = somename)` computes basic information about the package `somename`, and returns this in an object of class "packageInfo". (The structure of this class may change in future versions.) When used with the default value (NULL) for `lib.loc`, the attached packages are searched before the libraries.

**Value**

Normally `library` returns (invisibly) the list of attached packages, but `TRUE` or `FALSE` if `logical.return` is `TRUE`. When called as `library()` it returns an object of class "libraryIQR", and for `library(help=)`, one of class "packageInfo".

`require` returns (invisibly) a logical indicating whether the required package is available.

**Conflicts**

Handling of conflicts depends on the setting of the `conflicts.policy` option. If this option is not set, then conflicts result in warning messages if the argument `warn.conflicts` is `TRUE`. If the option is set to the character string "strict", then all unresolved conflicts signal errors. Conflicts can be resolved using the `mask.ok`, `exclude`, and `include.only` arguments to `library` and `require`. Defaults for `mask.ok` and `exclude` can be specified using `conflictRules`.

If the `conflicts.policy` option is set to the string "depends.ok" then conflicts resulting from attaching declared dependencies will not produce errors, but other conflicts will. This is likely to be the best setting for most users wanting some additional protection against unexpected conflicts.

The policy can be tuned further by specifying the `conflicts.policy` option as a named list with the following fields:

- `error`: logical; if `TRUE` treat unresolved conflicts as errors.
- `warn`: logical; unless `FALSE` issue a warning message when conflicts are found.
- `generics.ok`: logical; if `TRUE` ignore conflicts created by defining S4 generics for functions on the search path.
- `depends.ok`: logical; if `TRUE` do not treat conflicts with required packages as errors.
- `can.mask`: character vector of names of packages that are allowed to be masked. These would typically be base packages attached by default.

**Licenses**

Some packages have restrictive licenses, and there is a mechanism to allow users to be aware of such licenses. If `getOption("checkPackageLicense") == TRUE`, then at first use of a package with a not-known-to-be-FOSS (see below) license the user is asked to view and accept the license: a list
of accepted licenses is stored in file ‘~/.R/licensed’. In a non-interactive session it is an error to
use such a package whose license has not already been recorded as accepted.
As from R 3.4.0 the license check is done when the namespace is loaded.
Free or Open Source Software (FOSS, e.g. https://en.wikipedia.org/wiki/FOSS) packages
are determined by the same filters used by available.packages but applied to just the current
package, not its dependencies.
There can also be a site-wide file ‘R_HOME/etc/licensed.site’ of packages (one per line).

Formal methods

library takes some further actions when package methods is attached (as it is by default). Packages
can define formal generic functions as well as re-defining functions in other packages (notably
base) to be generic, and this information is cached whenever such a namespace is loaded after methods and re-defined functions (implicit generics) are excluded from the list of conflicts. The caching
and check for conflicts require looking for a pattern of objects; the search may be avoided by defining an object .noGenerics (with any value) in the namespace. Naturally, if the package does have
any such methods, this will prevent them from being used.

Note

library and require can only load/attach an installed package, and this is detected by having a
‘DESCRIPTION’ file containing a ‘Built:’ field.
Under Unix-alikes, the code checks that the package was installed under a similar operating sys-
tem as given by R$\cdot$.version$\cdot$platform (the canonical name of the platform under which R was
compiled), provided it contains compiled code. Packages which do not contain compiled code
can be shared between Unix-alikes, but not to other OSes because of potential problems with
line endings and OS-specific help files. If sub-architectures are used, the OS similarity is not
checked since the OS used to build may differ (e.g. i386-pc-linux-gnu code can be built on an x86_64-unknown-linux-gnu OS).
The package name given to library and require must match the name given in the package’s
‘DESCRIPTION’ file exactly, even on case-insensitive file systems such as are common on Windows
and macOS.

Examples

library()                # list all available packages
library(lib.loc = .Library) # list all packages in the default library
library(help = splines)  # documentation on package 'splines'
library(splines)         # attach package 'splines'
require(splines)         # the same
library.dynam

Loading DLLs from Packages

Description

Load the specified file of compiled code if it has not been loaded already, or unloads it.

Usage

library.dynam(chname, package, lib.loc, verbose = getOption("verbose"), file.ext = .Platform$dynlib.ext, ...)

library.dynam.unload(chname, libpath, verbose = getOption("verbose"), file.ext = .Platform$dynlib.ext)

.dynLibs(new)

Arguments

chname a character string naming a DLL (also known as a dynamic shared object or library) to load.
package a character vector with the name of package.
lib.loc a character vector describing the location of \( \mathcal{R} \) library trees to search through.
libpath the path to the loaded package whose DLL is to be unloaded.
verbose a logical value indicating whether an announcement is printed on the console before loading the DLL. The default value is taken from the verbose entry in the system \texttt{options}.
file.ext the extension (including "." if used) to append to the file name to specify the library to be loaded. This defaults to the appropriate value for the operating system.
additional arguments needed by some libraries that are passed to the call to \texttt{dyn.load} to control how the library and its dependencies are loaded.

new a list of "DLLInfo" objects corresponding to the DLLs loaded by packages. Can be missing.

Details

See \texttt{dyn.load} for what sort of objects these functions handle.

\texttt{library.dynam} is designed to be used inside a package rather than at the command line, and should really only be used inside \texttt{.onLoad}. The system-specific extension for DLLs (e.g., `.so` or `.sl` on Unix-alike systems, `.dll` on Windows) should not be added.

\texttt{library.dynam.unload} is designed for use in \texttt{.onUnload}: it unloads the DLL and updates the value of \texttt{.dynLibs()}

\texttt{.dynLibs} is used for getting (with no argument) or setting the DLLs which are currently loaded by packages (using \texttt{library.dynam}).

Value

If \texttt{chname} is not specified, \texttt{library.dynam} returns an object of class "DLLInfoList" corresponding to the DLLs loaded by packages.

If \texttt{chname} is specified, an object of class "DLLInfo" that identifies the DLL and which can be used in future calls is returned invisibly. Note that the class "DLLInfo" has a method for \$ which can be used to resolve native symbols within that DLL.

\texttt{library.dynam.unload} invisibly returns an object of class "DLLInfo" identifying the DLL successfully unloaded.

\texttt{.dynLibs} returns an object of class "DLLInfoList" corresponding corresponding to its current value.

Warning

Do not use \texttt{dyn.unload} on a DLL loaded by \texttt{library.dynam}: use \texttt{library.dynam.unload} to ensure that \texttt{.dynLibs} gets updated. Otherwise a subsequent call to \texttt{library.dynam} will be told the object is already loaded.

Note that whether or not it is possible to unload a DLL and then reload a revised version of the same file is OS-dependent: see the ‘Value’ section of the help for \texttt{dyn.unload}.

References

See Also

\texttt{getLoadedDLLs} for information on "DLLInfo" and "DLLInfoList" objects.

\texttt{.onLoad}, \texttt{library.dyn.load}, \texttt{.packages}, \texttt{.libPaths}

\texttt{SHLIB} for how to create suitable DLLs.
Examples

```r
## Which DLLs were dynamically loaded by packages?
library.dynam()

## More on library.dynam.unload() :
require(nlme)
nlme:::.onUnload # shows library.dynam.unload() call
detach("package:nlme") # by default, unload=FALSE , so,
tail(library.dynam(), 2)# nlme still there

## How to unload the DLL ?
## Best is to unload the namespace, unloadNamespace("nlme")
## If we need to do it separately which should be exceptional:
pd.file <- attr(packageDescription("nlme"), "file")
library.dynam.unload("nlme", libpath = sub("/Meta.*", '', pd.file))
tail(library.dynam(), 2)# 'nlme' is gone now
unloadNamespace("nlme") # now gives warning
```

Description

Functions to construct, coerce and check for both kinds of R lists.
Usage

```r
list(...)  
pairlist(...)  
```

```r
as.list(x, ...)  
## S3 method for class 'environment'
as.list(x, all.names = FALSE, sorted = FALSE, ...)  
as.pairlist(x)
```

```r
is.list(x)  
is.pairlist(x)

alist(...)
```

Arguments

... objects, possibly named.

x object to be coerced or tested.

all.names a logical indicating whether to copy all values or (default) only those whose
names do not begin with a dot.

sorted a logical indicating whether the names of the resulting list should be sorted (in-
creasingly). Note that this is somewhat costly, but may be useful for comparison
of environments.

Details

Almost all lists in R internally are Generic Vectors, whereas traditional dotted pair lists (as in LISP)
remain available but rarely seen by users (except as formals of functions).

The arguments to list or pairlist are of the form value or tag = value. The functions return
a list or dotted pair list composed of its arguments with each value either tagged or untagged,
depending on how the argument was specified.

alist handles its arguments as if they described function arguments. So the values are not evalu-
ated, and tagged arguments with no value are allowed whereas list simply ignores them. alist is
most often used in conjunction with formals.

as.list attempts to coerce its argument to a list. For functions, this returns the concatenation of
the list of formal arguments and the function body. For expressions, the list of constituent elements
is returned. as.list is generic, and as the default method calls as.vector(mode = "list") for
a non-list, methods for as.vector may be invoked. as.list turns a factor into a list of one-
element factors. Attributes may be dropped unless the argument already is a list or expression.
(This is inconsistent with functions such as as.character which always drop attributes, and is for
efficiency since lists can be expensive to copy.)

is.list returns TRUE if and only if its argument is a list or a pairlist of length > 0.
is.pairlist returns TRUE if and only if the argument is a pairlist or NULL (see below).

The "environment" method for as.list copies the name-value pairs (for names not beginning
with a dot) from an environment to a named list. The user can request that all named objects are
copied. Unless sorted = TRUE, the list is in no particular order (the order depends on the order
of creation of objects and whether the environment is hashed). No enclosing environments are
searched. (Objects copied are duplicated so this can be an expensive operation.) Note that there is
an inverse operation, the as.environment() method for list objects.
An empty pairlist, pairlist(), is the same as \texttt{NULL}. This is different from list(): some but not all operations will promote an empty pairlist to an empty list.

\texttt{as.pairlist} is implemented as \texttt{as.vector(x,"pairlist")}, and hence will dispatch methods for the generic function \texttt{as.vector}. Lists are copied element-by-element into a pairlist and the names of the list used as tags for the pairlist: the return value for other types of argument is undocumented.

\texttt{list}, \texttt{is.list} and \texttt{is.pairlist} are \texttt{primitive} functions.

'\texttt{plotmath}’ for the use of \texttt{list} in plot annotation.

\section*{Examples}

require(graphics)

# create a plotting structure
pts <- list(x = cars[,1], y = cars[,2])
plot(pts)

is.pairlist(.Options) # a user-level pairlist

## "pre-allocate" an empty list of length 5
vector("list", 5)

# Argument lists
f <- function() x
# Note the specification of a "..." argument:
formals(f) <- al <- alist(x = , y = 2+3, ... = )
f
al

## environment->list coercion

e1 <- new.env()
e1$a <- 10
e1$b <- 20
as.list(e1)

\begin{longtable}{l}
\texttt{list.files} & \textit{List the Files in a Directory/Folder} \\
\end{longtable}

\textbf{Description}

These functions produce a character vector of the names of files or directories in the named directory.
Usage

list.files(path = ".", pattern = NULL, all.files = FALSE,
full.names = FALSE, recursive = FALSE,
ignore.case = FALSE, include.dirs = FALSE, no.. = FALSE)

dir(path = ".", pattern = NULL, all.files = FALSE,
full.names = FALSE, recursive = FALSE,
ignore.case = FALSE, include.dirs = FALSE, no.. = FALSE)

list.dirs(path = ".", full.names = TRUE, recursive = TRUE)

Arguments

path      a character vector of full path names; the default corresponds to the working
directory, `getwd()`. Tilde expansion (see `path.expand`) is performed. Missing
values will be ignored. Elements with a marked encoding will be converted to
the native encoding (and if that fails, considered non-existent).

pattern   an optional regular expression. Only file names which match the regular expres-
sion will be returned.

all.files  a logical value. If FALSE, only the names of visible files are returned (following
Unix-style visibility, that is files whose name does not start with a dot). If TRUE,
all file names will be returned.

full.names a logical value. If TRUE, the directory path is prepended to the file names to give
a relative file path. If FALSE, the file names (rather than paths) are returned.

recursive  logical. Should the listing recurse into directories?

ignore.case logical. Should pattern-matching be case-insensitive?

include.dirs logical. Should subdirectory names be included in recursive listings? (They
always are in non-recursive ones).

no..       logical. Should both "." and ".." be excluded also from non-recursive listings?

Value

A character vector containing the names of the files in the specified directories (empty if there were
no files). If a path does not exist or is not a directory or is unreadable it is skipped.

The files are sorted in alphabetical order, on the full path if `full.names = TRUE`.

list.dirs implicitly has `all.files = TRUE` and if `recursive = TRUE`, the answer includes path
itself (provided it is a readable directory).

dir is an alias for `list.files`.

Note

File naming conventions are platform dependent. The pattern matching works with the case of file
names as returned by the OS.

On a POSIX filesystem recursive listings will follow symbolic links to directories.

Author(s)

Ross Ihaka, Brian Ripley
list2DF  

Create Data Frame From List

Description

Create a data frame from a list of variables.

Usage

list2DF(x = list(), nrow = NULL)

Arguments

x  
A list of variables for the data frame.

nrow  
An integer giving the desired number of rows for the data frame, or NULL (de-
default), in which case the maximal length of the elements of the list will be used.  
If necessary, list elements will be replicated to the same length given by the  
number of rows.

Details

Note that all list elements are taken “as is” (apart from possibly replicating to the same length).

Value

A data frame with the given variables.

See Also

data.frame

See Also

file.info, file.access and files for many more file handling functions and file.choose for interactive selection.
glob2rx to convert wildcards (as used by system file commands and shells) to regular expressions.  
Sys.glob for wildcard expansion on file paths.

Examples

list.files(R.home())
## Only files starting with a-l or r
## Note that a-l is locale-dependent, but using case-insensitive
## matching makes it unambiguous in English locales

dir("../..", pattern = "^[a-1r]", full.names = TRUE, ignore.case = TRUE)

list.dirs(R.home("doc"))
list.dirs(R.home("doc"), full.names = FALSE)
Examples

```r
## Create a data frame holding a list of character vectors and the
## corresponding lengths:
x <- list(character(), "A", c("B", "C"))
n <- lengths(x)
list2DF(list(x = x, n = n))

## Create data frames with no variables and the desired number of rows:
list2DF()
list2DF(nrow = 3L)
```

---

**list2env**

*From A List, Build or Add To an Environment*

**Description**

From a named list x, create an environment containing all list components as objects, or “multi-assign” from x into a pre-existing environment.

**Usage**

```r
list2env(x, envir = NULL, parent = parent.frame(),
      hash = (length(x) > 100), size = max(29L, length(x)))
```

**Arguments**

- `x` - a list, where `names(x)` must not contain empty ("") elements.
- `envir` - an environment or NULL.
- `parent` - (for the case `envir = NULL`): a parent frame aka enclosing environment, see `new.env`.
- `hash` - (for the case `envir = NULL`): logical indicating if the created environment should use hashing, see `new.env`.
- `size` - (in the case `envir = NULL`, `hash = TRUE`): hash size, see `new.env`.

**Details**

This will be very slow for large inputs unless hashing is used on the environment.

Environments must have uniquely named entries, but named lists need not: where the list has duplicate names it is the last element with the name that is used. Empty names throw an error.

**Value**

An environment, either newly created (as by `new.env`) if the `envir` argument was NULL, otherwise the updated environment `envir`. Since environments are never duplicated, the argument `envir` is also changed.

**Author(s)**

Martin Maechler
See Also

environment.new.env, as.environment; further, assign.

The (semantical) “inverse”: as.list.environment.

Examples

```r
L <- list(a = 1, b = 2:4, p = pi, ff = gl(3, 4, labels = LETTERS[1:3]))
e <- list2env(L)
ls(e)
stopifnot(ls(e) == sort(names(L)),
         identical(L$b, e$b)) # "$" working for environments as for lists

## consistency, when we do the inverse:
ll <- as.list(e) # -> dispatching to the as.list.environment() method
rbind(names(L), names(ll)) # not in the same order, typically,
# but the same content:
stopifnot(identical(L[sort.list(names(L))],
                          ll[sort.list(names(ll))]))

## now add to e -- can be seen as a fast "multi-assign":
list2env(list(abc = LETTERS, note = "just an example",
             df = data.frame(x = rnorm(20), y = rbinom(20, 1, pr = 0.2))),
envir = e)
utils::ls.str(e)
```

Description

Reload datasets written with the function save.

Usage

```r
load(file, envir = parent.frame(), verbose = FALSE)
```

Arguments

- `file`: a (readable binary-mode) connection or a character string giving the name of the file to load (when tilde expansion is done).
- `envir`: the environment where the data should be loaded.
- `verbose`: should item names be printed during loading?

Details

load can load R objects saved in the current or any earlier format. It can read a compressed file (see save) directly from a file or from a suitable connection (including a call to url).

A not-open connection will be opened in mode "rb" and closed after use. Any connection other than a gzfile or gzcon connection will be wrapped in gzcon to allow compressed saves to be handled: note that this leaves the connection in an altered state (in particular, binary-only), and that it needs to be closed explicitly (it will not be garbage-collected).
Only R objects saved in the current format (used since R 1.4.0) can be read from a connection. If no input is available on a connection a warning will be given, but any input not in the current format will result in an error.

Loading from an earlier version will give a warning about the ‘magic number’: magic numbers 1971:1977 are from R < 0.99.0, and RD[ABX]1 from R 0.99.0 to R 1.3.1. These are all obsolete, and you are strongly recommended to re-save such files in a current format.

The `verbose` argument is mainly intended for debugging. If it is TRUE, then as objects from the file are loaded, their names will be printed to the console. If `verbose` is set to an integer value greater than one, additional names corresponding to attributes and other parts of individual objects will also be printed. Larger values will print names to a greater depth.

Objects can be saved with references to namespaces, usually as part of the environment of a function or formula. Such objects can be loaded even if the namespace is not available: it is replaced by a reference to the global environment with a warning. The warning identifies the first object with such a reference (but there may be more than one).

### Value

A character vector of the names of objects created, invisibly.

### Warning

Saved R objects are binary files, even those saved with `ascii = TRUE`, so ensure that they are transferred without conversion of end of line markers. `load` tries to detect such a conversion and gives an informative error message.

`load(file)` replaces all existing objects with the same names in the current environment (typically your workspace, `.GlobalEnv`) and hence potentially overwrites important data. It is considerably safer to use `envir =` to load into a different environment, or to `attach(file)` which `load()`s into a new entry in the `search` path.

### See Also

`save`, `download.file`; further `attach` as wrapper for `load()`.

For other interfaces to the underlying serialization format, see `unserialize` and `readRDS`.

### Examples

```r
## save all data
xx <- pi # to ensure there is some data
save(list = ls(all = TRUE), file = "all.rda")
rm(xx)

## restore the saved values to the current environment
local({
  load("all.rda")
  ls()
})

xx <- exp(1:3)
## restore the saved values to the user's workspace
load("all.rda") ## which is here *equivalent* to
## load("all.rda", .GlobalEnv)
## This however annihilates all objects in .GlobalEnv with the same names !
```
xx # no longer exp(1:3)
rm(xx)
attach("all.rda") # safer and will warn about masked objects w/ same name in .GlobalEnv
ls(pos = 2)
## also typically need to cleanup the search path:
detach("file:all.rda")

## clean up (the example):
unlink("all.rda")

## Not run:
con <- url("http://some.where.net/R/data/example.rda")
## print the value to see what objects were created.
print(load(con))
close(con) # url() always opens the connection

## End(Not run)

### locales

#### Query or Set Aspects of the Locale

**Description**

Get details of or set aspects of the locale for the R process.

**Usage**

```r
Sys.getlocale(category = "LC_ALL")
Sys.setlocale(category = "LC_ALL", locale = "")
```

**Arguments**

- **category** character string. The following categories should always be supported: "LC_ALL", "LC_COLLATE", "LC_CTYPE", "LC_MONETARY", "LC_NUMERIC" and "LC_TIME". Some systems (not Windows) will also support "LC_MESSAGES", "LC_PAPER" and "LC_MEASUREMENT".
- **locale** character string. A valid locale name on the system in use. Normally "" (the default) will pick up the default locale for the system.

**Details**

The locale describes aspects of the internationalization of a program. Initially most aspects of the locale of R are set to "C" (which is the default for the C language and reflects North-American usage – also known as "POSIX"). R sets "LC_CTYPE" and "LC_COLLATE", which allow the use of a different character set and alphabetic comparisons in that character set (including the use of `sort`), "LC_MONETARY" (for use by `Sys.localeconv`) and "LC_TIME" may affect the behaviour of `as.POSIXlt` and `strptime` and functions which use them (but not `date`).

The first seven categories described here are those specified by POSIX. "LC_MESSAGES" will be "C" on systems that do not support message translation, and is not supported on Windows. Trying to use an unsupported category is an error for `Sys.setlocale`.
Note that setting category "LC_ALL" sets only categories "LC_COLLATE", "LC_CTYPE", "LC_MONETARY" and "LC_TIME".

Attempts to set an invalid locale are ignored. There may or may not be a warning, depending on the OS.

Attempts to change the character set (by Sys.setlocale("LC_CTYPE",), if that implies a different character set) during a session may not work and are likely to lead to some confusion.

Note that the LANGUAGE environment variable has precedence over "LC_MESSAGES" in selecting the language for message translation on most R platforms.

On platforms where ICU is used for collation the locale used for collation can be reset by icuSetCollate. Except on Windows, the initial setting is taken from the "LC_COLLATE" category, and it is reset when this is changed by a call to Sys.setlocale.

**Value**

A character string of length one describing the locale in use (after setting for Sys.setlocale), or an empty character string if the current locale settings are invalid or NULL if locale information is unavailable.

For category = "LC_ALL" the details of the string are system-specific: it might be a single locale name or a set of locale names separated by "/" (Solaris, macOS) or ";" (Windows, Linux). For portability, it is best to query categories individually: it is not necessarily the case that the result of foo <- Sys.getlocale() can be used in Sys.setlocale("LC_ALL", locale = foo).

**Available locales**

On most Unix-alikes the POSIX shell command locale -a will list the ‘available public’ locales. What that means is platform-dependent. On recent Linuxen this may mean ‘available to be installed’ as on some RPM-based systems the locale data is in separate RPMs. On Debian/Ubuntu the set of available locales is managed by OS-specific facilities such as locale-gen and locale -a lists those currently enabled.

For Windows, Microsoft moves its documentation frequently so a Web search is the best way to find current information.

**Warning**

Setting "LC_NUMERIC" to any value other than "C" may cause R to function anomalously, so gives a warning. Input conversions in R itself are unaffected, but the reading and writing of ASCII save files will be, as may packages which do their own input/output.

Setting it temporarily on a Unix-alike to produce graphical or text output may work well enough, but options(OutDec) is often preferable.

Almost all the output routines used by R itself under Windows ignore the setting of "LC_NUMERIC" since they make use of the Trio library which is not internationalized.

**Note**

Changing the values of locale categories whilst R is running ought to be noticed by the OS services, and usually is but exceptions have been seen (usually in collation services).
See Also

strptime for uses of category = "LC_TIME". Sys.localeconv for details of numerical and monetary representations.

11on_info gives some summary facts about the locale and its encoding.

The ‘R Installation and Administration’ manual for background on locales and how to find out locale names on your system.

Examples

Sys.getlocale()
Sys.getlocale("LC_TIME")

## Not run:
Sys.setlocale("LC_TIME", "de")  # Solaris: details are OS-dependent
Sys.setlocale("LC_TIME", "de_DE")  # Many Unix-alikes
Sys.setlocale("LC_TIME", "de_DE.UTF-8")  # Linux, macOS, other Unix-alikes
Sys.setlocale("LC_TIME", "de.DE.utf8")  # some Linux versions
Sys.setlocale("LC_TIME", "German")  # Windows

## End(Not run)
Sys.getlocale("LC_PAPER")  # may or may not be set

## Not run:
Sys.setlocale("LC_COLLATE", "C")  # turn off locale-specific sorting,
# usually (but not on all platforms)

## End(Not run)

log

Logarithms and Exponentials

Description

log computes logarithms, by default natural logarithms, log10 computes common (i.e., base 10) logarithms, and log2 computes binary (i.e., base 2) logarithms. The general form log(x, base) computes logarithms with base base.

log1p(x) computes log(1 + x) accurately also for |x| ≪ 1.

exp computes the exponential function.

expm1(x) computes exp(x) − 1 accurately also for |x| ≪ 1.

Usage

log(x, base = exp(1))
logb(x, base = exp(1))
log10(x)
log2(x)

log1p(x)

exp(x)

expm1(x)
Arguments

x a numeric or complex vector.

base a positive or complex number: the base with respect to which logarithms are computed. Defaults to $e^{\exp(1)}$.

Details

All except logb are generic functions: methods can be defined for them individually or via the Math group generic.

log10 and log2 are only convenience wrappers, but logs to bases 10 and 2 (whether computed via log or the wrappers) will be computed more efficiently and accurately where supported by the OS. Methods can be set for them individually (and otherwise methods for log will be used).

logb is a wrapper for log for compatibility with S. If (S3 or S4) methods are set for log they will be dispatched. Do not set S4 methods on logb itself.

All except log are primitive functions.

Value

A vector of the same length as x containing the transformed values. log(0) gives -Inf, and log(x) for negative values of x is NaN. exp(-Inf) is 0.

For complex inputs to the log functions, the value is a complex number with imaginary part in the range $[-\pi, \pi]$: which end of the range is used might be platform-specific.

S4 methods

exp, expm1, log, log10, log2 and log1p are S4 generic and are members of the Math group generic.

Note that this means that the S4 generic for log has a signature with only one argument, x, but that base can be passed to methods (but will not be used for method selection). On the other hand, if you only set a method for the Math group generic then base argument of log will be ignored for your class.

Source

log1p and expm1 may be taken from the operating system, but if not available there then they are based on the Fortran subroutine dlnrel by W. Fullerton of Los Alamos Scientific Laboratory (see https://www.netlib.org/slatec/fnlib/dlnrel.f) and (for small x) a single Newton step for the solution of log1p(y) = x respectively.

References

Trig, sqrt, Arithmetic.
Examples

\[
\begin{align*}
\log(\exp(3)) \\
\log_{10}(1e7) &= 7 \\
x &\leftarrow 10^{-(1+2*1:9)} \\
cbind(x, \log(1+x), \log1p(x), \exp(x)-1, \expm1(x))
\end{align*}
\]

Description

These operators act on raw, logical and number-like vectors.

Usage

\[
\begin{align*}
! x \\
x &\& y \\
x | y \\
x || y \\
xor(x, y)
\end{align*}
\]

isTRUE (x)

isFALSE (x)

Arguments

\[
x, y \quad \text{raw, logical or 'number-like' vectors (i.e., of types double (class numeric), integer and complex), or objects for which methods have been written.}
\]

Details

! indicates logical negation (NOT).
and and \&\& indicate logical AND and | and || indicate logical OR. The shorter form performs elementwise comparisons in much the same way as arithmetic operators. The longer form evaluates left to right examining only the first element of each vector. Evaluation proceeds only until the result is determined. The longer form is appropriate for programming control-flow and typically preferred in if clauses.
xor indicates elementwise exclusive OR.
isTRUE (x) is the same as \{ is.logical(x) && length(x) == 1 \&\& !is.na(x) \&\& x \}; isFALSE() is defined analogously. Consequently, if(isTRUE(cond)) may be preferable to if(cond) because of NAs.
In earlier \textsc{R} versions, isTRUE <-function(x) identical(x,TRUE), had the drawback to be false e.g., for x <-c(val = TRUE).
Numeric and complex vectors will be coerced to logical values, with zero being false and all non-zero values being true. Raw vectors are handled without any coercion for !, \&\& and |, xor, with these operators being applied bitwise (so ! is the 1s-complement).
The operators !, \& and | are generic functions: methods can be written for them individually or via the \texttt{Ops} (or S4 \texttt{Logic}, see below) group generic function. (See \texttt{Ops} for how dispatch is computed.)
NA is a valid logical object. Where a component of \( x \) or \( y \) is NA, the result will be NA if the outcome is ambiguous. In other words NA & TRUE evaluates to NA, but NA & FALSE evaluates to FALSE. See the examples below.

See Syntax for the precedence of these operators: unlike many other languages (including S) the AND and OR operators do not have the same precedence (the AND operators have higher precedence than the OR operators).

**Value**

For \(!\), a logical or raw vector(for raw \( x \)) of the same length as \( x \): names, dims and dimnames are copied from \( x \), and all other attributes (including class) if no coercion is done.

For \(|\), & and xor a logical or raw vector. If involving a zero-length vector the result has length zero. Otherwise, the elements of shorter vectors are recycled as necessary (with a warning when they are recycled only fractionally). The rules for determining the attributes of the result are rather complicated. Most attributes are taken from the longer argument, the first if they are of the same length. Names will be copied from the first if it is the same length as the answer, otherwise from the second if that is. For time series, these operations are allowed only if the series are compatible, when the class and tsp attribute of whichever is a time series (the same, if both are) are used. For arrays (and an array result) the dimensions and dimnames are taken from first argument if it is an array, otherwise the second.

For \(||\), \&& and \&isTRUE, a length-one logical vector.

**S4 methods**

\(!\), \& and \(\mid\) are S4 generics, the latter two part of the Logic group generic (and hence methods need argument names e1, e2).

**Note**

The elementwise operators are sometimes called as functions as e.g. \`\&\` \((x, y)\): see the description of how argument-matching is done in Ops.

**References**

**See Also**

TRUE or logical.

any and all for OR and AND on many scalar arguments.

Syntax for operator precedence.

bitwAnd for bitwise versions for integer vectors.

**Examples**

\[
y <- 1 + (x <- stats::rpois(50, lambda = 1.5) / 4 - 1)
x[(x > 0) & (x < 1)]  # all x values between 0 and 1
if (any(x == 0) || any(y == 0)) "zero encountered"
\]

## construct truth tables:
logical

Logical Vectors

Description

Create or test for objects of type "logical", and the basic logical constants.

Usage

TRUE
FALSE
T; F

logical(length = 0)
as.logical(x, ...)
is.logical(x)

Arguments

length A non-negative integer specifying the desired length. Double values will be coerced to integer: supplying an argument of length other than one is an error.

x object to be coerced or tested.

... further arguments passed to or from other methods.

Details

TRUE and FALSE are reserved words denoting logical constants in the R language, whereas T and F are global variables whose initial values set to these. All four are logical(1) vectors.

Logical vectors are coerced to integer vectors in contexts where a numerical value is required, with TRUE being mapped to 1L, FALSE to 0L and NA to NA_integer_.

Value

logical creates a logical vector of the specified length. Each element of the vector is equal to FALSE.

as.logical attempts to coerce its argument to be of logical type. In numeric and complex vectors, zeros are FALSE and non-zero values are TRUE. For factors, this uses the levels (labels). Like as.vector it strips attributes including names. Character strings c("T", "TRUE", "True", "true") are regarded as true, c("F", "FALSE", "False", "false") as false, and all others as NA.

is.logical returns TRUE or FALSE depending on whether its argument is of logical type or not.

References

See Also

NA, the other logical constant. Logical operators are documented in Logic.

Examples

```r
## non-zero values are TRUE
as.logical(c(pi,0))
if (length(letters)) cat("26 is TRUE
")

## logical interpretation of particular strings
carvec <- c("FALSE", "F", "False", "false", "fAlse", "0",
"TRUE", "T", "True", "true", "tRue", "1")
as.logical(carvec)

## factors are converted via their levels, so string conversion is used
as.logical(factor(carvec))
as.logical(factor(c(0,1))) # "0" and "1" give NA
```

Description

Vectors of $2^{31}$ or more elements were added in R 3.0.0.

Details

Prior to R 3.0.0, all vectors in R were restricted to at most $2^{31} - 1$ elements and could be indexed by integer vectors.

Currently all atomic (raw, logical, integer, numeric, complex, character) vectors, lists and expressions can be much longer on 64-bit platforms: such vectors are referred to as ‘long vectors’ and have a slightly different internal structure. In theory they can contain up to $2^{52}$ elements, but address space limits of current CPUs and OSes will be much smaller. Such objects will have a length that is expressed as a double, and can be indexed by double vectors.

Arrays (including matrices) can be based on long vectors provided each of their dimensions is at most $2^{31} - 1$: thus there are no 1-dimensional long arrays.

R code typically only needs minor changes to work with long vectors, maybe only checking that as.integer is not used unnecessarily for e.g. lengths. However, compiled code typically needs quite extensive changes. Note that the .C and .Fortran interfaces do not accept long vectors, so .Call (or similar) has to be used.

Because of the storage requirements (a minimum of 64 bytes per character string), character vectors are only going to be usable if they have a small number of distinct elements, and even then factors will be more efficient (4 bytes per element rather than 8). So it is expected that most of the usage of long vectors will be integer vectors (including factors) and numeric vectors.

Matrix algebra

It is now possible to use $m \times n$ matrices with more than 2 billion elements. Whether matrix algebra (including %*%, crossprod, svd, qr, solve and eigen) will actually work is somewhat implementation dependent, including the Fortran compiler used and if an external BLAS or LAPACK is used.
An efficient parallel BLAS implementation will often be important to obtain usable performance. For example on one particular platform chol on a 47,000 square matrix took about 5 hours with the internal BLAS, 21 minutes using an optimized BLAS on one core, and 2 minutes using an optimized BLAS on 16 cores.

---

**lower.tri**  
*Lower and Upper Triangular Part of a Matrix*

**Description**

Returns a matrix of logicals the same size of a given matrix with entries TRUE in the lower or upper triangle.

**Usage**

```r
lower.tri(x, diag = FALSE)  
upper.tri(x, diag = FALSE)
```

**Arguments**

- `x`: a matrix or other R object with `length(dim(x)) == 2`. For back compatibility reasons, when the above is not fulfilled, `as.matrix(x)` is called first.
- `diag`: logical. Should the diagonal be included?

**See Also**

`diag`, `matrix`; further `row` and `col` on which `lower.tri()` and `upper.tri()` are built.

**Examples**

```r
(m2 <- matrix(1:20, 4, 5))  
lower.tri(m2)  
m2[lower.tri(m2)] <- NA  
m2
```

---

**ls**  
*List Objects*

**Description**

`ls` and `objects` return a vector of character strings giving the names of the objects in the specified environment. When invoked with no argument at the top level prompt, `ls` shows what data sets and functions a user has defined. When invoked with no argument inside a function, `ls` returns the names of the function’s local variables: this is useful in conjunction with `browser`.

**Usage**

```r
ls(name, pos = -1L, envir = as.environment(pos),  
   all.names = FALSE, pattern, sorted = TRUE)  
objects(name, pos= -1L, envir = as.environment(pos),  
   all.names = FALSE, pattern, sorted = TRUE)
```
Arguments

- **name**: which environment to use in listing the available objects. Defaults to the *current* environment. Although called name for back compatibility, in fact this argument can specify the environment in any form; see the 'Details' section.

- **pos**: an alternative argument to name for specifying the environment as a position in the search list. Mostly there for back compatibility.

- **envir**: an alternative argument to name for specifying the environment. Mostly there for back compatibility.

- **all.names**: a logical value. If TRUE, all object names are returned. If FALSE, names which begin with a '.' are omitted.

- **pattern**: an optional regular expression. Only names matching pattern are returned. `glob2rx` can be used to convert wildcard patterns to regular expressions.

- **sorted**: logical indicating if the resulting character should be sorted alphabetically. Note that this is part of `ls()` may take most of the time.

Details

The **name** argument can specify the environment from which object names are taken in one of several forms: as an integer (the position in the search list); as the character string name of an element in the search list; or as an explicit environment (including using `sys.frame` to access the currently active function calls). By default, the environment of the call to `ls` or objects is used. The pos and envir arguments are an alternative way to specify an environment, but are primarily there for back compatibility.

Note that the order of strings for sorted = TRUE is locale dependent, see `Sys.getlocale`. If sorted = FALSE the order is arbitrary, depending if the environment is hashed, the order of insertion of objects,.....

References

See Also

- `glob2rx` for converting wildcard patterns to regular expressions.
- `ls.str` for a long listing based on `str.a`propos (or `find`) for finding objects in the whole search path; `grep` for more details on 'regular expressions'; `class`, `methods`, etc., for object-oriented programming.

Examples

```
.Ob <- 1
ls(pattern = "O")
ls(pattern = "O", all.names = TRUE)  # also shows ".[foo]"

# shows an empty list because inside myfunc no variables are defined
myfunc <- function() {ls()}
myfunc()

# define a local variable inside myfunc
myfunc <- function() {y <- 1; ls()}
myfunc()  # shows "y"
```
**make.names**

Make Syntactically Valid Names

**Description**

Make syntactically valid names out of character vectors.

**Usage**

```r
make.names(names, unique = FALSE, allow_ = TRUE)
```

**Arguments**

- `names` character vector to be coerced to syntactically valid names. This is coerced to character if necessary.
- `unique` logical; if TRUE, the resulting elements are unique. This may be desired for, e.g., column names.
- `allow_` logical. For compatibility with R prior to 1.9.0.

**Details**

A syntactically valid name consists of letters, numbers and the dot or underline characters and starts with a letter or the dot not followed by a number. Names such as ".2way" are not valid, and neither are the reserved words.

The definition of a letter depends on the current locale, but only ASCII digits are considered to be digits.

The character "X" is prepended if necessary. All invalid characters are translated to ".". A missing value is translated to ".NA". Names which match R keywords have a dot appended to them. Duplicated values are altered by make.unique.

**Value**

A character vector of same length as names with each changed to a syntactically valid name, in the current locale’s encoding.

**Warning**

Some OSes, notably FreeBSD, report extremely incorrect information about which characters are alphabetic in some locales (typically, all multi-byte locales including UTF-8 locales). However, R provides substitutes on Windows, macOS and AIX.

**Note**

Prior to R version 1.9.0, underscores were not valid in variable names, and code that relies on them being converted to dots will no longer work. Use allow_ = FALSE for back-compatibility.

allow_ = FALSE is also useful when creating names for export to applications which do not allow underline in names (for example, S-PLUS and some DBMSes).

**See Also**

make.unique, names, character, data.frame.
Examples

make.names(c("a and b", "a-and-b"), unique = TRUE)
# "a.and.b" "a.and.b.1"
make.names(c("a and b", "a_and_b"), unique = TRUE)
# "a.and.b" "a_and.b"
make.names(c("a and b", "a_and_b"), unique = TRUE, allow_ = FALSE)
# "a.and.b" "a.and.b.1"
make.names(c("", "X"), unique = TRUE)
# "X.1" "X" currently; R up to 3.0.2 gave "X" "X.1"

state.name[make.names(state.name) != state.name] # those 10 with a space

make.unique

Make Character Strings Unique

Description

Makes the elements of a character vector unique by appending sequence numbers to duplicates.

Usage

make.unique(names, sep = ".")

Arguments

names: a character vector
sep: a character string used to separate a duplicate name from its sequence number.

Details

The algorithm used by make.unique has the property that make.unique(c(A,B)) == make.unique(c(make.unique(A),B)).

In other words, you can append one string at a time to a vector, making it unique each time, and get the same result as applying make.unique to all of the strings at once.

If character vector A is already unique, then make.unique(c(A,B)) preserves A.

Value

A character vector of same length as names with duplicates changed, in the current locale’s encoding.

make.names
Examples

```r
make.unique(c("a", "a", "a"))
make.unique(c(make.unique(c("a", "a")), "a"))

make.unique(c("a", "a", "a.2", "a"))
make.unique(c(make.unique(c("a", "a")), "a.2", "a"))
```

```r
## Now show a bit where this is used:
trace(make.unique)
## Applied in data.frame() constructions:
(d1 <- data.frame(x = 1, x = 2, x = 3)) # direct
d2 <- data.frame(data.frame(x = 1, x = 2), x = 3) # pairwise
stopifnot(identical(d1, d2),
colnames(d1) == c("x", "x.1", "x.2"))
```

untrace(make.unique)

---

**mapply**

*Apply a Function to Multiple List or Vector Arguments*

**Description**

mapply is a multivariate version of `sapply`. mapply applies `FUN` to the first elements of each ... argument, the second elements, the third elements, and so on. Arguments are recycled if necessary.

**Usage**

```r
mapply(FUN, ..., MoreArgs = NULL, SIMPLIFY = TRUE,
USE.NAMES = TRUE)
```

**Arguments**

- `FUN` function to apply, found via `match.fun`.
- `...` arguments to vectorize over (vectors or lists of strictly positive length, or all of zero length). See also 'Details'.
- `MoreArgs` a list of other arguments to `FUN`.
- `SIMPLIFY` logical or character string; attempt to reduce the result to a vector, matrix or higher dimensional array; see the simplify argument of `sapply`.
- `USE.NAMES` logical; use the names of the first...argument, or if that is an unnamed character vector, use that vector as the names.

**Details**

mapply calls `FUN` for the values of ... (re-cycled to the length of the longest, unless any have length zero), followed by the arguments given in `MoreArgs`. The arguments in the call will be named if ... or `MoreArgs` are named.

Arguments with classes in ... will be accepted, and their subsetting and length methods will be used.
marginSums

Compute table margins

Description

For a contingency table in array form, compute the sum of table entries for a given margin or set of margins.

Usage

marginSums(x, margin = NULL)
margin.table(x, margin = NULL)

Arguments

x an array
margin a vector giving the margins to compute sums for. E.g., for a matrix 1 indicates rows, 2 indicates columns, c(1,2) indicates rows and columns. When x has named dimnames, it can be a character vector selecting dimension names.

Value

The relevant marginal table, or just the sum of all entries if margin has length zero. The class of x is copied to the output table if margin is non-NULL.

Note

margin.table is an earlier name, retained for back-compatibility.
**Description**

`mat.or.vec()` creates an `nr` by `nc` zero matrix if `nc` is greater than 1, and a zero vector of length `nr` if `nc` equals 1.

**Usage**

```r
mat.or.vec(nr, nc)
```

**Arguments**

- `nr`, `nc`  
  numbers of rows and columns.

**Examples**

```r
mat.or.vec(3, 1)
mat.or.vec(3, 2)
```
Value Matching

Description

match returns a vector of the positions of (first) matches of its first argument in its second.

%in% is a more intuitive interface as a binary operator, which returns a logical vector indicating if there is a match or not for its left operand.

Usage

match(x, table, nomatch = NA_integer_, incomparables = NULL)

x %in% table

Arguments

x  vector or NULL: the values to be matched. Long vectors are supported.

table  vector or NULL: the values to be matched against. Long vectors are not supported.

nomatch  the value to be returned in the case when no match is found. Note that it is coerced to integer.

incomparables  a vector of values that cannot be matched. Any value in x matching a value in this vector is assigned the nomatch value. For historical reasons, FALSE is equivalent to NULL.

Details

%in% is currently defined as

"%in%" <- function(x,table) match(x,table,nomatch = 0) > 0

Factors, raw vectors and lists are converted to character vectors, and then x and table are coerced to a common type (the later of the two types in R’s ordering, logical < integer < numeric < complex < character) before matching. If incomparables has positive length it is coerced to the common type.

Matching for lists is potentially very slow and best avoided except in simple cases.

Exactly what matches what is to some extent a matter of definition. For all types, NA matches NA and no other value. For real and complex values, NaN values are regarded as matching any other NaN value, but not matching NA, where for complex x, real and imaginary parts must match both (unless containing at least one NA).

Character strings will be compared as byte sequences if any input is marked as "bytes", and otherwise are regarded as equal if they are in different encodings but would agree when translated to UTF-8 (see Encoding).

That %in% never returns NA makes it particularly useful in if conditions.
Value

A vector of the same length as \( x \).

match: An integer vector giving the position in \( table \) of the first match if there is a match, otherwise nomatch.

If \( x[i] \) is found to equal \( table[j] \) then the value returned in the \( i \)-th position of the return value is \( j \), for the smallest possible \( j \). If no match is found, the value is nomatch.

%in%: A logical vector, indicating if a match was located for each element of \( x \) : thus the values are TRUE or FALSE and never NA.

References

See Also

\texttt{pmatch} and \texttt{charmatch} for (partial) string matching, \texttt{match.arg}, etc for function argument matching. \texttt{findInterval} similarly returns a vector of positions, but finds numbers within intervals, rather than exact matches.

\texttt{is.element} for an S-compatible equivalent of \%in\%.

\texttt{unique} (and \texttt{duplicated}) are using the same definitions of “match” or “equality” as \texttt{match()}, and these are less strict than \( == \), e.g., for \texttt{NA} and \texttt{NaN} in numeric or complex vectors, or for strings with different encodings, see also above.

Examples

## The intersection of two sets can be defined via \texttt{match}():
## Simple version:
## intersect <- function(x, y) y[match(x, y, nomatch = 0)]
## intersect # the R function in base is slightly more careful
## intersect(1:10, 7:20)
1:10 %in% c(1,3,5,9)
sstr <- c("c","ab","B","bba","c","NA","@","bla","a","Ba","%")
sstr[sstr %in% c(letters, LETTERS)]

"%w/o%" <- function(x, y) x[!x %in% y] #-- x without y
(1:10) %w/o% c(3,7,12)

## Note that \texttt{setdiff()} is very similar and typically makes more sense:
## c(1:6,7:2) %w/o% c(3,7,12) # -> keeps duplicates
## setdiff(c(1:6,7:2), c(3,7,12)) # -> unique values

## Illuminating example about NA matching
r <- c(1, NA, NaN)
zN <- c(complex(real = NA , imaginary = r ), complex(real = r , imaginary = NA ),
       complex(real = r , imaginary = NaN), complex(real = NaN, imaginary = r ))
zM <- cbind(Re=Re(zN), Im=Im(zN), match = match(zN, zN))
rownames(zM) <- format(zN)
zN #-- many "NA's" (= 1) and the four non-NA's (3 different ones, at 7,9,10)
length(zN) # 12
unique(zN) # the "NA" and the 3 different non-NA NaN's
stopifnot(identical(unique(zN), zN[c(1, 7,9,10)]))
## very strict equality would have 4 duplicates (of 12):
symnum(outer(zN, zN, Vectorize(identical,c("x","y")),
FALSE,FALSE,FALSE,FALSE))
## removing "(very strictly) duplicates",
i <- c(5,8,11,12)  # we get 8 pairwise non-identicals :
Ixy <- outer(zN[-i], zN[-i], Vectorize(identical,c("x","y")),
FALSE,FALSE,FALSE,FALSE)
stopifnot(identical(Ixy, diag(8) == 1))

---

**match.arg**

**Argument Verification Using Partial Matching**

**Description**

match.arg matches arg against a table of candidate values as specified by choices, where NULL means to take the first one.

**Usage**

match.arg(arg, choices, several.ok = FALSE)

**Arguments**

- **arg**  
  a character vector (of length one unless several.ok is TRUE) or NULL.
- **choices**  
  a character vector of candidate values
- **several.ok**  
  logical specifying if arg should be allowed to have more than one element.

**Details**

In the one-argument form match.arg(arg), the choices are obtained from a default setting for the formal argument arg of the function from which match.arg was called. (Since default argument matching will set arg to choices, this is allowed as an exception to the ‘length one unless several.ok is TRUE’ rule, and returns the first element.)

Matching is done using pmatch, so arg may be abbreviated.

**Value**

The unabbreviated version of the exact or unique partial match if there is one; otherwise, an error is signalled if several.ok is false, as per default. When several.ok is true and more than one element of arg has a match, all unabbreviated versions of matches are returned.

**See Also**

pmatch, match.fun, match.call
Examples

```
require(stats)
## Extends the example for 'switch'
center <- function(x, type = c("mean", "median", "trimmed")) {
    type <- match.arg(type)
    switch(type,
        mean = mean(x),
        median = median(x),
        trimmed = mean(x, trim = .1))
}
x <- rcauchy(10)
center(x, "t") # Works
center(x, "med") # Works
try(center(x, "m")) # Error
stopifnot(identical(center(x), center(x, "mean")),
          identical(center(x, NULL), center(x, "mean")))
```

```r
## Allowing more than one match:
match.arg(c("gauss", "rect", "ep"),
          c("gaussian", "epanechnikov", "rectangular", "triangular"),
          several.ok = TRUE)
```

match.call

Argument Matching

Description

match.call returns a call in which all of the specified arguments are specified by their full names.

Usage

```
match.call(definition = sys.function(sys.parent()),
call = sys.call(sys.parent()),
expand.dots = TRUE,
envir = parent.frame(2L))
```

Arguments

- `definition` a function, by default the function from which `match.call` is called. See details.
- `call` an unevaluated call to the function specified by `definition`, as generated by `call`.
- `expand.dots` logical. Should arguments matching `...` in the call be included or left as a `...` argument?
- `envir` an environment, from which the `...` in `call` are retrieved, if any.

Details

‘function’ on this help page means an interpreted function (also known as a ‘closure’): `match.call` does not support primitive functions (where argument matching is normally positional).

`match.call` is most commonly used in two circumstances:
match.fun

- To record the call for later re-use: for example most model-fitting functions record the call as an element call of the list they return. Here the default expand.dots = TRUE is appropriate.

- To pass most of the call to another function, often model.frame. Here the common idiom is that expand.dots = FALSE is used, and the . . . element of the matched call is removed. An alternative is to explicitly select the arguments to be passed on, as is done in lm.

Calling match.call outside a function without specifying definition is an error.

Value

An object of class call.

References

See Also

sys.call() is similar, but does not expand the argument names; call, pmatch, match.arg, match.fun.

Examples

match.call(get, call("get", "abc", i = FALSE, p = 3))
## -> get(x = "abc", pos = 3, inherits = FALSE)
fun <- function(x, lower = 0, upper = 1) {
  structure((x - lower) / (upper - lower), CALL = match.call())
}
fun(4 * atan(1), u = pi)

match.fun

Extract a Function Specified by Name

Description

When called inside functions that take a function as argument, extract the desired function object while avoiding undesired matching to objects of other types.

Usage

match.fun(FUN, descend = TRUE)

Arguments

FUN item to match as function: a function, symbol or character string. See 'Details'.
descend logical; control whether to search past non-function objects.
Details

match.fun is not intended to be used at the top level since it will perform matching in the parent of the caller.

If FUN is a function, it is returned. If it is a symbol (for example, enclosed in backquotes) or a character vector of length one, it will be looked up using get in the environment of the parent of the caller. If it is of any other mode, it is attempted first to get the argument to the caller as a symbol (using substitute twice), and if that fails, an error is declared.

If descend = TRUE, match.fun will look past non-function objects with the given name; otherwise if FUN points to a non-function object then an error is generated.

This is used in base functions such as apply, lapply, outer, and sweep.

Value

A function matching FUN or an error is generated.

Bugs

The descend argument is a bit of a misnomer and probably not actually needed by anything. It may go away in the future.

It is impossible to fully foolproof this. If one attaches a list or data frame containing a length-one character vector with the same name as a function, it may be used (although namespaces will help).

Author(s)

Peter Dalgaard and Robert Gentleman, based on an earlier version by Jonathan Rougier.

See Also

match.arg, get

Examples

# Same as get("*"):  
match.fun("*")  
# Overwrite outer with a vector  
outer <- 1:5  
try(match.fun(outer, descend = FALSE)) #-> Error: not a function  
match.fun(outer) # finds it anyway  
is.function(match.fun("outer")) # as well

MathFun

Miscellaneous Mathematical Functions

Description

abs(x) computes the absolute value of x, sqrt(x) computes the (principal) square root of x, √x.  
The naming follows the standard for computer languages such as C or Fortran.
Usage

abs(x)
sqrt(x)

Arguments

x

Arguments

x a numeric or complex vector or array.

Details

These are internal generic primitive functions: methods can be defined for them individually or via the Math group generic. For complex arguments (and the default method), z, \( \text{abs}(z) = \text{Mod}(z) \) and \( \text{sqrt}(z) = z^{0.5} \).

abs(x) returns an integer vector when x is integer or logical.

S4 methods

Both are S4 generic and members of the Math group generic.

References

See Also

Arithmetic for simple, log for logarithmic, sin for trigonometric, and Special for special mathematical functions.

'plotmath' for the use of sqrt in plot annotation.

Examples

```r
require(stats) # for spline
require(graphics)
x <- -9:9
plot(xx, sqrt(abs(xx)), col = "red")
lines(spline(xx, sqrt(abs(xx)), n=101), col = "pink")
```

matmult

Matrix Multiplication

Description

Multiplies two matrices, if they are conformable. If one argument is a vector, it will be promoted to either a row or column matrix to make the two arguments conformable. If both are vectors of the same length, it will return the inner product (as a matrix).

Usage

x %*% y
Arguments

\( x, y \) numeric or complex matrices or vectors.

Details

When a vector is promoted to a matrix, its names are not promoted to row or column names, unlike as.matrix.

Promotion of a vector to a 1-row or 1-column matrix happens when one of the two choices allows \( x \) and \( y \) to get conformable dimensions.

This operator is S4 generic but not S3 generic. S4 methods need to be written for a function of two arguments named \( x \) and \( y \).

Value

A double or complex matrix product. Use drop to remove dimensions which have only one level.

Note

The propagation of NaN/Inf values, precision, and performance of matrix products can be controlled by options("matprod").

References

See Also

For matrix crossproducts, crossprod() and tcrossprod() are typically preferable. matrix, Arithmetic, diag.

Examples

\[
\begin{align*}
x & \leftarrow 1:4 \\
(z & \leftarrow x \times x) \quad \text{# scalar ("inner") product (1 x 1 matrix)} \\
drop(z) & \quad \text{# as scalar} \\
y & \leftarrow \text{diag}(x) \\
z & \leftarrow \text{matrix}(1:12, \text{ncol} = 3, \text{nrow} = 4) \\
y \times z \\
y \times x \\
x \times z
\end{align*}
\]

matrix

Matrices

Description

matrix creates a matrix from the given set of values.

as.matrix attempts to turn its argument into a matrix.

is.matrix tests if its argument is a (strict) matrix.
matrix

Usage

matrix(data = NA, nrow = 1, ncol = 1, byrow = FALSE, dimnames = NULL)

as.matrix(x, ...)  # S3 method for class 'data.frame'
as.matrix(x, rownames.force = NA, ...)

is.matrix(x)

Arguments

data an optional data vector (including a list or expression vector). Non-atomic
classed R objects are coerced by as.vector and all attributes discarded.
nrow the desired number of rows.
ncol the desired number of columns.
byrow logical. If FALSE (the default) the matrix is filled by columns, otherwise the
matrix is filled by rows.
dimnames A dimnames attribute for the matrix: NULL or a list of length 2 giving the row
and column names respectively. An empty list is treated as NULL, and a list of
length one as row names. The list can be named, and the list names will be used
as names for the dimensions.
x an R object.
... additional arguments to be passed to or from methods.
rownames.force logical indicating if the resulting matrix should have character (rather than NULL)
rownames. The default, NA, uses NULL rownames if the data frame has 'auto-
matic' row.names or for a zero-row data frame.

Details

If one of nrow or ncol is not given, an attempt is made to infer it from the length of data and the
other parameter. If neither is given, a one-column matrix is returned.

If there are too few elements in data to fill the matrix, then the elements in data are recycled. If
data has length zero, NA of an appropriate type is used for atomic vectors (0 for raw vectors) and
NULL for lists.
is.matrix returns TRUE if x is a vector and has a "dim" attribute of length 2 and FALSE otherwise. Note that a data.frame is not a matrix by this test. The function is generic: you can write methods
to handle specific classes of objects, see InternalMethods.
as.matrix is a generic function. The method for data frames will return a character matrix if
there is only atomic columns and any non-(numeric/logical/complex) column, applying as.vector
to factors and format to other non-character columns. Otherwise, the usual coercion hierarchy
(logical < integer < double < complex) will be used, e.g., all-logical data frames will be coerced to
a logical matrix, mixed logical-integer will give a integer matrix, etc.
The default method for as.matrix calls as.vector(x), and hence e.g. coerces factors to character
vectors.
When coercing a vector, it produces a one-column matrix, and promotes the names (if any) of the
vector to the rownames of the matrix.
is.matrix is a primitive function.
The print method for a matrix gives a rectangular layout with dimnames or indices. For a list matrix, the entries of length not one are printed in the form ‘integer,7’ indicating the type and length.

Note

If you just want to convert a vector to a matrix, something like

```r
dim(x) <- c(nx, ny)
dimnames(x) <- list(row_names, col_names)
```

will avoid duplicating `x`.

References

See Also

data.matrix, which attempts to convert to a numeric matrix.

A matrix is the special case of a two-dimensional array. Since R 4.0.0, inherits(m,"array") is true for a matrix `m`.

Examples

```r
is.matrix(as.matrix(1:10))
!is.matrix(warpbreaks) # data.frame, NOT matrix!
warpbreaks[1:10,]
as.matrix(warpbreaks[1:10,]) # using as.matrix.data.frame(.) method

## Example of setting row and column names
mdat <- matrix(c(1,2,3, 11,12,13), nrow = 2, ncol = 3, byrow = TRUE,
dimnames = list(c("row1", "row2"),
c("C.1", "C.2", "C.3")))
mdat
```

maxCol

Find Maximum Position in Matrix

Description

Find the maximum position for each row of a matrix, breaking ties at random.

Usage

```r
max.col(m, ties.method = c("random", "first", "last"))
```

Arguments

- `m` numerical matrix
- `ties.method` a character string specifying how ties are handled, "random" by default; can be abbreviated; see ‘Details’.
Details

When `ties.method = "random"`, as per default, ties are broken at random. In this case, the determination of a tie assumes that the entries are probabilities: there is a relative tolerance of $10^{-5}$, relative to the largest (in magnitude, omitting infinity) entry in the row.

If `ties.method = "first"`, `max.col` returns the column number of the first of several maxima in every row, the same as `unname(apply(m,1,which.max))`. Correspondingly, `ties.method = "last"` returns the last of possibly several indices.

Value

Index of a maximal value for each row, an integer vector of length `nrow(m)`.

References

See Also

`which.max` for vectors.

Examples

```r
table(mc <- max.col(swiss)) # mostly "1" and "5", 5 x "2" and once "4"
swiss[unique(print(mr <- max.col(t(swiss)))) , ] # 3 33 45 45 33 6

set.seed(1) # reproducible example:
(mm <- rbind(x = round(2*stats::runif(12)),
y = round(5*stats::runif(12)),
z = round(8*stats::runif(12))))
## Not run:
x  1  1  1  2  0  2  2  1  1  0  0  0
y  3  2  4  2  4  5  2  4  5  1  3  1
z  2  3  0  3  7  3  4  5  4  1  7  5
## End(Not run)
## column indices of all row maxima :
utils::str(lapply(1:3, function(i) which(mm[i,] == max(mm[i,]))))
max.col(mm) ; max.col(mm) # "random"
max.col(mm, "first") # -> 4 6 5
max.col(mm, "last") # -> 7 9 11
```

mean

**Arithmetic Mean**

Description

Generic function for the (trimmed) arithmetic mean.
memCompress

Usage

mean(x, ...)

## Default S3 method:
mean(x, trim = 0, na.rm = FALSE, ...)

Arguments

x
An R object. Currently there are methods for numeric/logical vectors and date, date-time and time interval objects. Complex vectors are allowed for trim = 0, only.

trim
the fraction (0 to 0.5) of observations to be trimmed from each end of x before the mean is computed. Values of trim outside that range are taken as the nearest endpoint.

na.rm
a logical value indicating whether NA values should be stripped before the computation proceeds.

...
进一步 arguments passed to or from other methods.

Value

If trim is zero (the default), the arithmetic mean of the values in x is computed, as a numeric or complex vector of length one. If x is not logical (coerced to numeric), numeric (including integer) or complex, NA_real_ is returned, with a warning.

If trim is non-zero, a symmetrically trimmed mean is computed with a fraction of trim observations deleted from each end before the mean is computed.

References

See Also

weighted.mean, mean.POSIXct, colMeans for row and column means.

Examples

x <- c(0:10, 50)
xm <- mean(x)
c(xm, mean(x, trim = 0.10))

memCompress

In-memory Compression and Decompression

Description

In-memory compression or decompression for raw vectors.
Usage

```r
memCompress(from, type = c("gzip", "bzip2", "xz", "none"))
memDecompress(from,
    type = c("unknown", "gzip", "bzip2", "xz", "none"),
    asChar = FALSE)
```

Arguments

- `from`: A raw vector. For `memCompress` a character vector will be converted to a raw vector with character strings separated by "\n". Types "gzip" and "xz" support long raw vectors as from R 4.0.0.
- `type`: character string, the type of compression. May be abbreviated to a single letter, defaults to the first of the alternatives.
- `asChar`: logical: should the result be converted to a character string? NB: character strings have a limit of $2^{31} - 1$ bytes, so raw vectors should be used for large inputs.

Details

- `type = "none"` passes the input through unchanged, but may be useful if `type` is a variable.
- `type = "unknown"` attempts to detect the type of compression applied (if any): this will always succeed for `bzip2` compression, and will succeed for other forms if there is a suitable header. It will auto-detect the ‘magic’ header ("\x1f\x8b") added to files by the `gzip` program (and to files written by `gzfile`), but `memCompress` does not add such a header. (It supports RFC 1950 format, sometimes known as ‘zlib’ format, for compression and decompression and RFC 1952 for decompression only.)

  - gzip compression uses whatever is the default compression level of the underlying library (usually 6).
  - bzip2 compression always adds a header ("BZh"). The underlying library only supports in-memory (de)compression of up to $2^{31} - 1$ elements. Compression is equivalent to `bzip2 -9` (the default).
  - Compressing with `type = "xz"` is equivalent to compressing a file with `xz -9e` (including adding the ‘magic’ header): decompression should cope with the contents of any file compressed by `xz` version 4.999 and later, as well as by some versions of `lzma`. There are other versions, in particular ‘raw’ streams, that are not currently handled.
  - All the types of compression can expand the input: for "gzip" and "bzip2" the maximum expansion is known and so `memCompress` can always allocate sufficient space. For "xz" it is possible (but extremely unlikely) that compression will fail if the output would have been too large.

Value

A raw vector or a character string (if `asChar = TRUE`).

See Also

- `connections`
- `extSoftVersion` for the versions of the zlib, bzip2 and xz libraries in use.
- https://en.wikipedia.org/wiki/Data_compression for background on data compression,
memlimits

Query and Set Heap Size Limits

Description
Query and set the maximal size of the vector heap and the maximal number of heap nodes for the current R process.

Usage

```r
mem.maxVSize(vsize = 0)
mem.maxNSize(nsize = 0)
```

Arguments

- `vsize` numeric; new size limit in Mb.
- `nsize` numeric; new maximal node number.

Details
New Limits lower than current usage are ignored. Specifying a size of Inf sets the limit to the maximal possible value for the platform.

The default maximal values are unlimited on most platforms, but can be adjusted using environment variables as described in Memory. On macOS a lower default vector heap limit is used to protect against the R process being killed when macOS over-commits memory.

Adjusting the maximal number of nodes is rarely necessary. Adjusting the vector heap size limit can be useful on macOS in particular but should be done with caution.

Value
The current or new value, in Mb for `mem.maxVSize`. Inf is returned if the current value is unlimited.
Memory

Description

How \( R \) manages its workspace.

Details

\( R \) has a variable-sized workspace. There are (rarely-used) command-line options to control its minimum size, but no longer any to control the maximum size.

\( R \) maintains separate areas for fixed and variable sized objects. The first of these is allocated as an array of cons cells (Lisp programmers will know what they are, others may think of them as the building blocks of the language itself, parse trees, etc.), and the second are thrown on a heap of ‘Vcells’ of 8 bytes each. Each cons cell occupies 28 bytes on a 32-bit build of \( R \), (usually) 56 bytes on a 64-bit build.

The default values are (currently) an initial setting of 350k cons cells and 6Mb of vector heap. Note that the areas are not actually allocated initially: rather these values are the sizes for triggering garbage collection. These values can be set by the command line options ‘--min-nsize’ and ‘--min-vsize’ (or if they are not used, the environment variables \( R\_NSIZE \) and \( R\_VSIZE \)) when \( R \) is started. Thereafter \( R \) will grow or shrink the areas depending on usage, never decreasing below the initial values. The maximal vector heap size can be set with the environment variable \( R\_MAX\_VSIZE \).

How much time \( R \) spends in the garbage collector will depend on these initial settings and on the trade-off the memory manager makes, when memory fills up, between collecting garbage to free up unused memory and growing these areas. The strategy used for growth can be specified by setting the environment variable \( R\_GC\_MEM\_GROW \) to an integer value between 0 and 3. This variable is read at start-up. Higher values grow the heap more aggressively, thus reducing garbage collection time but using more memory.

You can find out the current memory consumption (the heap and cons cells used as numbers and megabytes) by typing \( gc() \) at the \( R \) prompt. Note that following \( gcinfo(TRUE) \), automatic garbage collection always prints memory use statistics.

The command-line option ‘--max-ppsize’ controls the maximum size of the pointer protection stack. This defaults to 50000, but can be increased to allow deep recursion or large and complicated calculations to be done. \( Note \) that parts of the garbage collection process goes through the full reserved pointer protection stack and hence becomes slower when the size is increased. Currently the maximum value accepted is 500000.

See Also

*An Introduction to R* for more command-line options.

\texttt{Memory-limits} for the design limitations.

\texttt{gc} for information on the garbage collector and total memory usage, \texttt{object.size(a)} for the (approximate) size of \( R \) object \( a \). \texttt{memory.profile} for profiling the usage of cons cells.
**Memory-limits**

**Memory Limits in R**

**Description**

\( \mathbb{R} \) holds objects it is using in virtual memory. This help file documents the current design limitations on large objects: these differ between 32-bit and 64-bit builds of \( \mathbb{R} \).

**Details**

Currently \( \mathbb{R} \) runs on 32- and 64-bit operating systems, and most 64-bit OSes (including Linux, Solaris, Windows and macOS) can run either 32- or 64-bit builds of \( \mathbb{R} \). The memory limits depend mainly on the build, but for a 32-bit build of \( \mathbb{R} \) on Windows they also depend on the underlying OS version.

\( \mathbb{R} \) holds all objects in virtual memory, and there are limits based on the amount of memory that can be used by all objects:

- There may be limits on the size of the heap and the number of cons cells allowed – see Memory – but these are usually not imposed.
- There is a limit on the (user) address space of a single process such as the \( \mathbb{R} \) executable. This is system-specific, and can depend on the executable.
- The environment may impose limitations on the resources available to a single process: Windows’ versions of \( \mathbb{R} \) do so directly.

Error messages beginning cannot allocate vector of size indicate a failure to obtain memory, either because the size exceeded the address-space limit for a process or, more likely, because the system was unable to provide the memory. Note that on a 32-bit build there may well be enough free memory available, but not a large enough contiguous block of address space into which to map it.

There are also limits on individual objects. The storage space cannot exceed the address limit, and if you try to exceed that limit, the error message begins cannot allocate vector of length. The number of bytes in a character string is limited to \( 2^{31} - 1 \approx 2 \times 10^9 \), which is also the limit on each dimension of an array.

**Unix**

The address-space limit is system-specific: 32-bit OSes imposes a limit of no more than 4Gb; it is often 3Gb. Running 32-bit executables on a 64-bit OS will have similar limits: 64-bit executables will have an essentially infinite system-specific limit (e.g., 128Tb for Linux on x86_64 cpus).

See the OS/shell’s help on commands such as `limit` or `ulimit` for how to impose limitations on the resources available to a single process. For example a bash user could use

```
ulimit -t 600 -v 4000000
```

whereas a csh user might use

```
limit cputime 10m
limit vmemoryuse 4096m
```

to limit a process to 10 minutes of CPU time and (around) 4Gb of virtual memory. (There are other options to set the RAM in use, but they are not generally honoured.)
Windows

The address-space limit is 2Gb under 32-bit Windows unless the OS’s default has been changed to allow more (up to 3Gb). See https://docs.microsoft.com/en-gb/windows/desktop/Memory/physical-address-extension and https://docs.microsoft.com/en-gb/windows/desktop/Memory/4-gigabyte-tuning. Under most 64-bit versions of Windows the limit for a 32-bit build of R is 4Gb: for the oldest ones it is 2Gb. The limit for a 64-bit build of R (imposed by the OS) is 8Tb.

It is not normally possible to allocate as much as 2Gb to a single vector in a 32-bit build of R even on 64-bit Windows because of preallocations by Windows in the middle of the address space.

Under Windows, R imposes limits on the total memory allocation available to a single session as the OS provides no way to do so: see memory.size and memory.limit.

See Also

object.size(a) for the (approximate) size of R object a.

memory.profile

Profile the Usage of Cons Cells

Description

Lists the usage of the cons cells by SEXPREC type.

Usage

memory.profile()

Details

The current types and their uses are listed in the include file ‘Rinternals.h’.

Value

A vector of counts, named by the types. See typeof for an explanation of types.

See Also

gc for the overall usage of cons cells. Rprofmem and tracemem allow memory profiling of specific code or objects, but need to be enabled at compile time.

Examples

memory.profile()
merge **Merge Two Data Frames**

**Description**

Merge two data frames by common columns or row names, or do other versions of database *join* operations.

**Usage**

```r
merge(x, y, ...)  
## Default S3 method:
merge(x, y, ...)  
## S3 method for class 'data.frame'
merge(x, y, by = intersect(names(x), names(y)),
    by.x = by, by.y = by, all = FALSE, all.x = all, all.y = all,
    sort = TRUE, suffixes = c(".x",".y"), no.dups = TRUE,
    incomparables = NULL, ...)  
```

**Arguments**

- `x, y` data frames, or objects to be coerced to one.
- `by, by.x, by.y` specifications of the columns used for merging. See ‘Details’.
- `all` logical; `all = L` is shorthand for `all.x = L` and `all.y = L`, where `L` is either `TRUE` or `FALSE`.
- `all.x` logical; if `TRUE`, then extra rows will be added to the output, one for each row in `x` that has no matching row in `y`. These rows will have NAs in those columns that are usually filled with values from `y`. The default is `FALSE`, so that only rows with data from both `x` and `y` are included in the output.
- `all.y` logical; analogous to `all.x`.
- `sort` logical. Should the result be sorted on the `by` columns?
- `suffixes` a character vector of length 2 specifying the suffixes to be used for making unique the names of columns in the result which are not used for merging (appearing in `by` etc).
- `no.dups` logical indicating that suffixes are appended in more cases to avoid duplicated column names in the result. This was implicitly false before R version 3.5.0.
- `incomparables` values which cannot be matched. See `match`. This is intended to be used for merging on one column, so these are incomparable values of that column.
- `...` arguments to be passed to or from methods.

**Details**

`merge` is a generic function whose principal method is for data frames: the default method coerces its arguments to data frames and calls the "data.frame" method.

By default the data frames are merged on the columns with names they both have, but separate specifications of the columns can be given by `by.x` and `by.y`. The rows in the two data frames that
match on the specified columns are extracted, and joined together. If there is more than one match, all possible matches contribute one row each. For the precise meaning of ‘match’, see \texttt{match}.

Columns to merge on can be specified by name, number or by a logical vector: the name "row.names" or the number 0 specifies the row names. If specified by name it must correspond uniquely to a named column in the input.

If \texttt{by} or both \texttt{by.x} and \texttt{by.y} are of length 0 (a length zero vector or NULL), the result, \texttt{r}, is the \textit{Cartesian product} of \texttt{x} and \texttt{y}, i.e., \texttt{dim(r) = c(nrow(x)*nrow(y), ncol(x) + ncol(y))}.

If \texttt{all.x} is true, all the non matching cases of \texttt{x} are appended to the result as well, with NA filled in the corresponding columns of \texttt{y}; analogously for \texttt{all.y}.

If the columns in the data frames not used in merging have any common names, these have suffixes (".x" and ".y" by default) appended to try to make the names of the result unique. If this is not possible, an error is thrown.

If a \texttt{by.x} column name matches one of \texttt{y}, and if \texttt{no.dups} is true (as by default), the \texttt{y} version gets suffixed as well, avoiding duplicate column names in the result.

The complexity of the algorithm used is proportional to the length of the answer.

In SQL database terminology, the default value of \texttt{all} = FALSE gives a \textit{natural join}, a special case of an \textit{inner join}. Specifying \texttt{all.x} = TRUE gives a \textit{left (outer) join}, \texttt{all.y} = TRUE a \textit{right (outer) join}, and both (\texttt{all} = TRUE) a \textit{(full) outer join}. DBMSes do not match NULL records, equivalent to \texttt{incomparables = NA} in \texttt{R}.

\section*{Value}

A data frame. The rows are by default lexicographically sorted on the common columns, but for \texttt{sort} = FALSE are in an unspecified order. The columns are the common columns followed by the remaining columns in \texttt{x} and then those in \texttt{y}. If the matching involved row names, an extra character column called \texttt{Row.names} is added at the left, and in all cases the result has `automatic` row names.

\section*{Note}

This is intended to work with data frames with vector-like columns: some aspects work with data frames containing matrices, but not all.

Currently long vectors are not accepted for inputs, which are thus restricted to less than \(2^{31}\) rows. That restriction also applies to the result for 32-bit platforms.

\section*{See Also}

\texttt{data.frame}, \texttt{by}, \texttt{cbind}.

\texttt{dendrogram} for a class which has a \texttt{merge} method.

\section*{Examples}

\begin{verbatim}
authors <- data.frame(  
    ## I(*) : use character columns of names to get sensible sort order  
surname = I(c("Tukey", "Venables", "Tierney", "Ripley", "McNeil")),  
nationality = c("US", "Australia", "US", "UK", "Australia"),  
deceased = c("yes", rep("no", 4)))  
authorN <- within(authors, { name <- surname; rm(surname) })  
books <- data.frame(  
    name = I(c("Tukey", "Venables", "Tierney", "Ripley", "Ripley", "McNeil", "R Core")),  
title = c("Exploratory Data Analysis",  

dendrogram for a class which has a merge method.

\end{verbatim}
"Modern Applied Statistics ...",
"LISP-STAT",
"Spatial Statistics", "Stochastic Simulation",
"Interactive Data Analysis",
"An Introduction to R"),
other.author = c(NA, "Ripley", NA, NA, NA, NA,
"Venables & Smith")

(m0 <- merge(authorN, books))
(m1 <- merge(authors, books, by.x = "surname", by.y = "name"))
m2 <- merge(books, authors, by.x = "name", by.y = "surname")
stopifnot(exprs = {
  identical(m0, m2[, names(m0)])
  as.character(m1[, 1]) == as.character(m2[, 1])
  all.equal(m1[, -1], m2[, -1][ names(m1)[-1] ])
  identical(dim(merge(m1, m2, by = NULL)),
    c(nrow(m1)*nrow(m2), ncol(m1)*ncol(m2)))
})

## "R core" is missing from authors and appears only here:
merge(authors, books, by.x = "surname", by.y = "name", all = TRUE)

## example of using 'incomparables'
x <- data.frame(k1 = c(NA,NA,3,4,5), k2 = c(1,NA,NA,4,5), data = 1:5)
y <- data.frame(k1 = c(NA,2,NA,4,5), k2 = c(NA,NA,3,4,5), data = 1:5)
merge(x, y, by = c("k1","k2")) # NA's match
merge(x, y, by = "k1") # NA's match, so 6 rows
merge(x, y, by = "k2", incomparables = NA) # 2 rows

---

### Diagnostic Messages

Generate a diagnostic message from its arguments.

#### Usage

```r
message(..., domain = NULL, appendLF = TRUE)
suppressMessages(expr, classes = "message")
packageStartupMessage(..., domain = NULL, appendLF = TRUE)
suppressPackageStartupMessages(expr)
.makeMessage(..., domain = NULL, appendLF = FALSE)
```

#### Arguments

- `...`: zero or more objects which can be coerced to character (and which are pasted together with no separator) or (for message only) a single condition object.
- `domain`: see `gettext`. If NA, messages will not be translated, see also the note in `stop`.
- `appendLF`: logical: should messages given as a character string have a newline appended?
expression to evaluate.

classes character, indicating which classes of messages should be suppressed.

Details

message is used for generating ‘simple’ diagnostic messages which are neither warnings nor errors, but nevertheless represented as conditions. Unlike warnings and errors, a final newline is regarded as part of the message, and is optional. The default handler sends the message to the stderr() connection.

If a condition object is supplied to message it should be the only argument, and further arguments will be ignored, with a warning.

While the message is being processed, a muffleMessage restart is available.

suppressMessages evaluates its expression in a context that ignores all ‘simple’ diagnostic messages.

packageStartupMessage is a variant whose messages can be suppressed separately by suppressPackageStartupMessages. (They are still messages, so can be suppressed by suppressMessages.)

尕makeMessage is a utility used by message, warning and stop to generate a text message from the ... arguments by possible translation (see gettext) and concatenation (with no separator).

See Also

warning and stop for generating warnings and errors; conditions for condition handling and recovery.

ggettext for the mechanisms for the automated translation of text.

Examples

message("ABC", "DEF")
suppressMessages(message("ABC"))

testit <- function() {
  message("testing package startup messages")
  packageStartupMessage("initializing ...", appendLF = FALSE)
  Sys.sleep(1)
  packageStartupMessage(" done")
}

testit()
suppressPackageStartupMessages(testit())
suppressMessages(testit())

missing Does a Formal Argument have a Value?

missing can be used to test whether a value was specified as an argument to a function.
mode

Usage

missing(x)

Arguments

x a formal argument.

Details

missing(x) is only reliable if x has not been altered since entering the function: in particular it will always be false after x <- match.arg(x).

The example shows how a plotting function can be written to work with either a pair of vectors giving x and y coordinates of points to be plotted or a single vector giving y values to be plotted against their indices.

Currently missing can only be used in the immediate body of the function that defines the argument, not in the body of a nested function or a local call. This may change in the future.

This is a ‘special’ primitive function: it must not evaluate its argument.

References

See Also

substitute for argument expression; NA for missing values in data.

Examples

myplot <- function(x, y) {
  if(missing(y)) {
    y <- x
    x <- 1:length(y)
  }
  plot(x, y)
}

mode

The (Storage) Mode of an Object

Description

Get or set the type or storage mode of an object.

Usage

mode(x)

mode(x) <- value

storage.mode(x)

storage.mode(x) <- value
Arguments

- **x**: any R object.
- **value**: a character string giving the desired mode or ‘storage mode’ (type) of the object.

Details

Both `mode` and `storage.mode` return a character string giving the (storage) mode of the object — often the same — both relying on the output of `typeof(x)`, see the example below.

`mode(x) <-"newmode"` changes the mode of object `x` to `newmode`. This is only supported if there is an appropriate as. newmode function, for example "logical", "integer", "double", "complex", "raw", "character", "list", "expression", "name", "symbol" and "function". Attributes are preserved (but see below).

`storage.mode(x) <-"newmode"` is a more efficient primitive version of `mode<-`, which works for "newmode" which is one of the internal types (see `typeof`), but not for "single". Attributes are preserved.

As storage mode "single" is only a pseudo-mode in R, it will not be reported by mode or storage.mode: use `attr(object,"Csingle")` to examine this. However, `mode<-` can be used to set the mode to "single", which sets the real mode to "double" and the "Csingle" attribute to TRUE. Setting any other mode will remove this attribute.

Note (in the examples below) that some calls have mode "(" which is S compatible.

Mode names

Modes have the same set of names as types (see `typeof`) except that

- types "integer" and "double" are returned as "numeric".
- types "special" and "builtin" are returned as "function".
- type "symbol" is called mode "name".
- type "language" is returned as "(" or "call".

References

See Also

- `typeof` for the R-internal ‘mode’, `type.convert`, `attributes`.

Examples

```r
require(stats)
sapply(options(), mode)

cex3 <- c("NULL", "1", "1:1", "l1", "list(l1)", "data.frame(x = 1)",
  "pairlist(pi)", "c", "lm", "formals(lm)\[[1]\]", "formals(lm)\[[2]\]",
  "y ~ x","expression((1))\[[1]\]", 
  "y ~ x","expression(x <- pi)\[[1]\]"[1]","y ~ x"]\[[1]\]"
lex3 <- sapply(cex3, function(x) eval(str2lang(x)))
mex3 <- t(sapply(lex3,
  function(x) c(typeof(x), storage.mode(x), mode(x))))
```
NA

Description

NA is a logical constant of length 1 which contains a missing value indicator. NA can be coerced to any other vector type except raw. There are also constants `NA_integer_`, `NA_real_`, `NA_complex_` and `NA_character_` of the other atomic vector types which support missing values: all of these are reserved words in the R language.

The generic function `is.na` indicates which elements are missing.

The generic function `is.na<-` sets elements to NA.

The generic function anyNA implements any(is.na(x)) in a possibly faster way (especially for atomic vectors).

Usage

```r
NA
is.na(x)
anyNA(x, recursive = FALSE)
```

```r
## S3 method for class 'data.frame'
is.na(x)

is.na(x) <- value
```

Arguments

- `x` an R object to be tested: the default method for is.na and anyNA handle atomic vectors, lists, pairlists, and NULL.
- `recursive` logical: should anyNA be applied recursively to lists and pairlists?
- `value` a suitable index vector for use with x.

Details

The NA of character type is distinct from the string "NA". Programmers who need to specify an explicit missing string should use `NA_character_` (rather than "NA") or set elements to NA using `is.na<-`.

is.na and anyNA are generic: you can write methods to handle specific classes of objects, see InternalMethods.

Function `is.na<-` may provide a safer way to set missingness. It behaves differently for factors, for example.
Numerical computations using NA will normally result in NA: a possible exception is where NaN is also involved, in which case either might result (which may depend on the R platform). However, this is not guaranteed and future CPUs and/or compilers may behave differently.

Logical computations treat NA as a missing TRUE/FALSE value, and so may return TRUE or FALSE if the expression does not depend on the NA operand.

The default method for anyNA handles atomic vectors without a class and NULL. It calls any(is.na(x)) on objects with classes and for recursive = FALSE, on lists and pairlists.

Value

The default method for is.na applied to an atomic vector returns a logical vector of the same length as its argument x, containing TRUE for those elements marked NA or, for numeric or complex vectors, NaN, and FALSE otherwise. (A complex value is regarded as NA if either its real or imaginary part is NA or NaN.) dim, dimnames and names attributes are copied to the result.

The default methods also work for lists and pairlists:

For is.na, elementwise the result is false unless that element is a length-one atomic vector and the single element of that vector is regarded as NA or NaN (note that any is.na method for the class of the element is ignored).

anyNA(recursive = FALSE) works the same way as is.na; anyNA(recursive = TRUE) applies anyNA (with method dispatch) to each element.

The data frame method for is.na returns a logical matrix with the same dimensions as the data frame, and with dimnames taken from the row and column names of the data frame.

anyNA(NULL) is false; is.na(NULL) is logical(0) (no longer warning since R version 3.5.0).

References

See Also

NaN, is.nan, etc., and the utility function complete.cases.
na.action, na.omit, na.fail on how methods can be tuned to deal with missing values.

Examples

is.na(c(1, NA))    #> FALSE  TRUE
is.na(paste(c(1, NA))) #> FALSE FALSE

(xx <- c(0:4))
xx <- c(2, 4)
xx          #> 0 NA 2 NA 4
anyNA(xx)   # TRUE

# Some logical operations do not return NA
c(TRUE, FALSE) & NA
c(TRUE, FALSE) | NA

## Measure speed difference in a favourable case:
## the difference depends on the platform, on most ca 3x.
```r
x <- 1:10000; x[5000] <- NaN # coerces x to be double
if(require("microbenchmark")) { # does not work reliably on all platforms
  print(microbenchmark(any(is.na(x)), anyNA(x)))
} else {
  nSim <- 2^13
  print(rbind(is.na = system.time(replicate(nSim, any(is.na(x)))),
             anyNA = system.time(replicate(nSim, anyNA(x)))))
}

## anyNA() can work recursively with lists:
LL <- list(1:5, c(NA, 5:8), c("A","NA"), c("a", NA_character_))
L2 <- LL[c(1,3)]
sapply(LL, anyNA); c(anyNA(LL), anyNA(LL, TRUE))
sapply(L2, anyNA); c(anyNA(L2), anyNA(L2, TRUE))

## ... lists, and hence data frames, too:
DN <- dd <- USJudgeRatings; DN[3,6] <- NA
anyNA(dd) # FALSE
anyNA(DN) # TRUE
```

### Description

A ‘name’ (also known as a ‘symbol’) is a way to refer to R objects by name (rather than the value of the object, if any, bound to that name).

as.name and as.symbol are identical: they attempt to coerce the argument to a name.

is.symbol and the identical is.name return TRUE or FALSE depending on whether the argument is a name or not.

### Usage

```r
as.symbol(x)
is.symbol(x)
as.name(x)
is.name(x)
```

### Arguments

- **x**
  - object to be coerced or tested.

### Details

Names are limited to 10,000 bytes (and were to 256 bytes in versions of R before 2.13.0).

as.name first coerces its argument internally to a character vector (so methods for as.character are not used). It then takes the first element and provided it is not "", returns a symbol of that name (and if the element is NA_character_, the name is "NA").

as.name is implemented as `as.vector(x,"symbol")`, and hence will dispatch methods for the generic function `as.vector`.

is.name and is.symbol are **primitive** functions.
Value

For as.name and as.symbol, an R object of type "symbol" (see typeof).

For is.name and is.symbol, a length-one logical vector with value TRUE or FALSE.

Note

The term ‘symbol’ is from the LISP background of R, whereas ‘name’ has been the standard S term for this.

References

See Also

call, is.language. For the internal object mode, typeof.

plotmath for another use of ‘symbol’.

Examples

an <- as.name("arrg")
is.name(an) # TRUE
mode(an)  # name
typeof(an) # symbol

---

names  The Names of an Object

Description

Functions to get or set the names of an object.

Usage

names(x)
names(x) <- value

Arguments

x  an R object.
value a character vector of up to the same length as x, or NULL.
Details

`names` is a generic accessor function, and `names<-` is a generic replacement function. The default methods get and set the "names" attribute of a vector (including a list) or pairlist.

For an `environment` `env`, `names(env)` gives the names of the corresponding list, i.e., `names(as.list(env, all.names = TRUE))` which are also given by `ls(env, all.names = TRUE, sorted = FALSE)`. If the environment is used as a hash table, `names(env)` are its "keys".

If `value` is shorter than `x`, it is extended by character `NAs` to the length of `x`.

It is possible to update just part of the names attribute via the general rules: see the examples. This works because the expression there is evaluated as `z <- "names<-"(z, "c2")`. The name "" is special: it is used to indicate that there is no name associated with an element of an atomic or generic vector. Subscripting by "" will match nothing (not even elements which have no name).

A name can be character `NA`, but such a name will never be matched and is likely to lead to confusion. Both are primitive functions.

Value

For `names`, `NULL` or a character vector of the same length as `x`. (`NULL` is given if the object has no names, including for objects of types which cannot have names.) For an environment, the length is the number of objects in the environment but the order of the names is arbitrary.

For `names<-`, the updated object. (Note that the value of `names(x) <- value` is that of the assignment, `value`, not the return value from the left-hand side.)

Note

For vectors, the names are one of the `attributes` with restrictions on the possible values. For pairlists, the names are the tags and converted to and from a character vector.

For a one-dimensional array the names attribute really is `dimnames[[1]]`.

Formally classed aka "S4" objects typically have `slotNames()` (and no `names()`).

References

See Also

`slotNames`, `dimnames`.

Examples

```r
# print the names attribute of the islands data set
names(islands)

# remove the names attribute
names(islands) <- NULL
islands
rm(islands) # remove the copy made

z <- list(a = 1, b = "c", c = 1:3)
names(z)
```
#change just the name of the third element.
names(z)[3] <- "c2"

z <- 1:3
names(z)

## assign just one name
names(z)[2] <- "b"
z

---

nargs

The Number of Arguments to a Function

Description

When used inside a function body, nargs returns the number of arguments supplied to that function, including positional arguments left blank.

Usage

nargs()

Details

The count includes empty (missing) arguments, so that foo(x,,z) will be considered to have three arguments (see ‘Examples’). This can occur in rather indirect ways, so for example x[] might dispatch a call to `[.some_method` (x,) which is considered to have two arguments.

This is a primitive function.

References

See Also

args, formals and sys.call.

Examples

tst <- function(a, b = 3, ...) {nargs()}
tst() # 0
tst(clicketyclack) # 1 (even non-existing)
tst(c1, a2, rr3) # 3

foo <- function(x, y, z, w) {
  cat("call was ", deparse(match.call()), "\n", sep = "")
  nargs()
}
tst() # 0
tst(, , 3) # 3
foo(z = 3) # 1, even though this is the same call
nargs() # not really meaningful

---

**nchar**

*Count the Number of Characters (or Bytes or Width)*

**Description**

`nchar` takes a character vector as an argument and returns a vector whose elements contain the sizes of the corresponding elements of `x`. Internally, it is a generic, for which methods can be defined (see `InternalMethods`).

`nzchar` is a fast way to find out if elements of a character vector are non-empty strings.

**Usage**

```r
nchar(x, type = "chars", allowNA = FALSE, keepNA = NA)
nzchar(x, keepNA = FALSE)
```

**Arguments**

- `x` character vector, or a vector to be coerced to a character vector. Giving a factor is an error.
- `type` character string: partial matching to one of c("bytes","chars","width"). See ‘Details’.
- `allowNA` logical: should NA be returned for invalid multibyte strings or "bytes"-encoded strings (rather than throwing an error)?
- `keepNA` logical: should NA be returned where ever `x` is NA? If false, `nchar()` returns 2, as that is the number of printing characters used when strings are written to output, and `nzchar()` is TRUE. The default for `nchar()`, NA, means to use `keepNA = TRUE unless type is "width". Used to be (implicitly) hard coded to FALSE in R versions ≤ 3.2.0.

**Details**

The ‘size’ of a character string can be measured in one of three ways (corresponding to the `type` argument):

- `bytes` The number of bytes needed to store the string (plus in C a final terminator which is not counted).
- `chars` The number of characters.
- `width` The number of columns `cat` will use to print the string in a monospaced font. The same as `chars` if this cannot be calculated.

These will often be the same, and almost always will be in single-byte locales (but note how `type` determines the default for `keepNA`). There will be differences between the first two with multibyte character sequences, e.g. in UTF-8 locales.

The internal equivalent of the default method of `as.character` is performed on `x` (so there is no method dispatch). If you want to operate on non-vector objects passing them through `deparse` first will be required.
Value

For `nchar`, an integer vector giving the sizes of each element. For missing values (i.e., `NA`, i.e., `NA_character_`), `nchar()` returns `NA_integer_` if `keepNA` is true, and 2, the number of printing characters, if false.

type = "width" gives (an approximation to) the number of columns used in printing each element in a terminal font, taking into account double-width, zero-width and ‘composing’ characters.

If `allowNA = TRUE` and an element is detected as invalid in a multi-byte character set such as UTF-8, its number of characters and the width will be `NA`. Otherwise the number of characters will be non-negative, so `!is.na(nchar(x,"chars",TRUE))` is a test of validity.

A character string marked with "bytes" encoding (see Encoding) has a number of bytes, but neither a known number of characters nor a width, so the latter two types are `NA` if `allowNA = TRUE`, otherwise an error.

Names, dims and dimnames are copied from the input.

For `nzchar`, a logical vector of the same length as `x`, true if and only if the element has non-zero length; if the element is `NA`, `nzchar()` is true when `keepNA` is false, as by default, and `NA` otherwise.

Note

This does not by default give the number of characters that will be used to print() the string. Use `encodeString` to find that. Where character strings have been marked as UTF-8, the number of characters and widths will be computed in UTF-8, even though printing may use escapes such as ‘<U+2642>’ in a non-UTF-8 locale.

The concept of ‘width’ is a slippery one even in a monospaced font. Some human languages have the concept of combining characters, in which two or more characters are rendered together: an example would be "y\u3086", which is two characters of width one: combining characters are given width zero, and there are other zero-width characters such as the zero-width space "\u200b".

Some East Asian languages have ‘wide’ characters, ideographs which are conventionally printed across two columns when mixed with ASCII and other ‘narrow’ characters in those languages. The problem is that whether a computer prints wide characters over two or one columns depends on the font, with it not being uncommon to use two columns in a font intended for East Asian users and a single column in a ‘Western’ font. Unicode has encodings for ‘fullwidth’ versions of ASCII characters and ‘halfwidth’ versions of Katakana (Japanese) and Hangul (Korean) characters. Then there is the ‘East Asian Ambiguous class’ (Greek, Cyrillic, signs, some accented Latin chars, etc), for which the historical practice was to use two columns in East Asia and one elsewhere. The width quoted by `nchar` for characters in that class (and some others) depends on the locale, being one except in some East Asian locales on some OSes (notably Windows).

Control characters are given width zero.

`strwidth` giving width of strings for plotting; `paste`, `substr`, `strsplit`
Examples

```r
x <- c("asfef", "qwerty", "yuiop[", "b", "stuff.blah.yech")
nchar(x)
# 5 6 6 1 15

nchar(deparse(mean))
# 18 17 <-- unless mean differs from base::mean

x[3] <- NA; x
nchar(x, keepNA= TRUE) # 5 6 NA 1 15
nchar(x, keepNA=FALSE) # 5 6 2 1 15
stopifnot(identical(nchar(x ), nchar(x, keepNA= TRUE)),
  identical(nchar(x, "w"), nchar(x, keepNA=FALSE)),
  identical(is.na(x), is.na(nchar(x)))))
```

```r
## nchar() for all three types :
nchars <- function(x, ...)
  vapply(c("chars", "bytes", "width"),
    function(tp) nchar(x, tp, ...), integer(length(x)))

nchars("\u200b") # in R versions (>= 2015-09-xx):
## chars bytes width
## 1 3 0
```

```r
data.frame(x, nchars(x)) ## all three types : same unless for NA
## force the same by forcing 'keepNA':
(ncT <- nchars(x, keepNA = TRUE)) ## .... NA NA NA ....
(ncF <- nchars(x, keepNA = FALSE))## .... 2 2 2 ....
stopifnot(apply(ncT, 1, function(.) length(unique(.))) == 1,
  apply(ncF, 1, function(.) length(unique(.))) == 1)
```

---

nlevels

The Number of Levels of a Factor

Description

Return the number of levels which its argument has.

Usage

```r
nlevels(x)
```

Arguments

- `x` an object, usually a factor.

Details

This is usually applied to a factor, but other objects can have levels.

The actual factor levels (if they exist) can be obtained with the `levels` function.

Value

The length of `levels(x)`, which is zero if `x` has no levels.
See Also

levels, factor.

Examples

nlevels(gl(3, 7)) # = 3

noquote

Class for ‘no quote’ Printing of Character Strings

Description

Print character strings without quotes.

Usage

noquote(obj, right = FALSE)

## S3 method for class 'noquote'
print(x, quote = FALSE, right = FALSE, ...)

## S3 method for class 'noquote'
c(..., recursive = FALSE)

Arguments

obj any R object, typically a vector of character strings.
right optional logical eventually to be passed to print(), used by
print.default(), indicating whether or not strings should be right aligned.
x an object of class "noquote".
quote, ... further options passed to next methods, such as print.
recursive for compatibility with the generic c function.

Details

noquote returns its argument as an object of class "noquote". There is a method for c() and
subscript method ("[.noquote") which ensures that the class is not lost by subsetting. The print
method (print.noquote) prints character strings without quotes ("...").

If right is specified in a call print(x, right=*)

These functions exist both as utilities and as an example of using (S3) class and object orientation.

methods, class, print.
**Examples**

```r
letters
nql <- noquote(letters)
nql
nql[1:4] <- "oh"
nql[1:12]

cmp.logical <- function(log.v)
{
  ## Purpose: compact printing of logicals
  log.v <- as.logical(log.v)
  noquote(if(length(log.v) == 0)"()" else c("."","[1 + log.v])
}

chmat <- as.matrix(format(stackloss)) # a "typical" character matrix
## noquote(*, right=TRUE) so it prints exactly like a data frame
chmat <- noquote(chmat, right = TRUE)
chmat
```

---

**norm**  
*Compute the Norm of a Matrix*

**Description**

Computes a matrix norm of \( x \) using LAPACK. The norm can be the one ("O") norm, the infinity ("I") norm, the Frobenius ("F") norm, the maximum modulus ("M") among elements of a matrix, or the "spectral" or "2"-norm, as determined by the value of \( \text{type} \).

**Usage**

```r
norm(x, type = c("O", "I", "F", "M", "2"))
```

**Arguments**

- **x**: numeric matrix; note that packages such as Matrix define more norm() methods.
- **type**: character string, specifying the type of matrix norm to be computed. A character indicating the type of norm desired.
  - "O", "o" or "1" specifies the one norm, (maximum absolute column sum);
  - "I" or "i" specifies the infinity norm (maximum absolute row sum);
  - "F" or "f" specifies the Frobenius norm (the Euclidean norm of \( x \) treated as if it were a vector);
  - "M" or "m" specifies the maximum modulus of all the elements in \( x \); and
  - "2" specifies the "spectral" or 2-norm, which is the largest singular value (svd) of \( x \).

The default is "O". Only the first character of type[1] is used.
Details

The base method of norm() calls the LAPACK function dlange.

Note that the 1-, Inf- and "M" norm is faster to calculate than the Frobenius one.

Unsuccessful results from the underlying LAPACK code will result in an error giving a positive error code: these can only be interpreted by detailed study of the FORTRAN code.

Value

The matrix norm, a non-negative number.

Source

Except for norm = "2", the LAPACK routine DLANGE.
LAPACK is from https://www.netlib.org/lapack/.

References

See Also

rcond for the (reciprocal) condition number.

Examples

(x1 <- cbind(1, 1:10))
norm(x1)
norm(x1, "I")
norm(x1, "M")
stopifnot(all.equal(norm(x1, "F"),
                     sqrt(sum(x1^2))))

hilbert <- function(n) { i <- 1:n; 1 / outer(i - 1, i, "+")}
h9 <- hilbert(9)
## all 5 types of norm:
(nTyp <- eval(formals(base::norm)$type))
sapply(nTyp, norm, x = h9)

normalizePath(path, winslash = NA, mustWork = NA)
normalizePath

Arguments

path character vector of file paths.

winslash the separator to be used on Windows – ignored elsewhere. Must be one of c("/", "\")

mustWork logical: if TRUE then an error is given if the result cannot be determined; if NA then a warning.

Details

Tilde-expansion (see path.expand) is first done on paths. Where the Unix-alike platform supports it attempts to turn paths into absolute paths in their canonical form (no ‘’/’’, ‘’./’’ nor symbolic links). It relies on the POSIX system function realpath: if the platform does not have that (we know of no current example) then the result will be an absolute path but might not be canonical. Even where realpath is used the canonical path need not be unique, for example via hard links or multiple mounts.

On Windows it converts relative paths to absolute paths, resolves symbolic links, converts short names for path elements to long names and ensures the separator is that specified by winslash. It will match each path element case-insensitively or case-sensitively as during the usual name lookup and return the canonical case. It relies on Windows API function GetFinalPathNameByHandle and in case of an error (such as insufficient permissions) it currently falls back to the R 3.6 (and older) implementation, which relies on GetFullPathName and GetLongPathName with limitations described in the Notes section. An attempt is made not to introduce UNC paths in presence of mapped drives or symbolic links: if GetFinalPathNameByHandle returns a UNC path, but GetLongPathName returns a path starting with a drive letter, R falls back to the R 3.6 (and older) implementation. UTF-8-encoded paths not valid in the current locale can be used.

mustWork = FALSE is useful for expressing paths for use in messages.

Value

A character vector.

If an input is not a real path the result is system-dependent (unless mustWork = TRUE, when this should be an error). It will be either the corresponding input element or a transformation of it into an absolute path.

Converting to an absolute file path can fail for a large number of reasons. The most common are

• One of more components of the file path does not exist.
• A component before the last is not a directory, or there is insufficient permission to read the directory.
• For a relative path, the current directory cannot be determined.
• A symbolic link points to a non-existent place or links form a loop.
• The canonicalized path would be exceed the maximum supported length of a file path.

Note

The canonical form of paths may not be what you expect. For example, on macOS absolute paths such as ‘/tmp’ and ‘/var’ are symbolic links. On Linux, a path produced by bash process substitution is a symbolic link (such as ‘/proc/fd/63’) to a pipe and there is no canonical form of such path. In R 3.6 and older on Windows, symlinks will not be resolved and the long names for path elements will be returned with the case in which they are in path, which may not be canonical in case-insensitive folders.
Examples

```r
# random tempdir
cat(normalizePath(c(R.home(), tempdir())), sep = "\n")
```

NotYet

<table>
<thead>
<tr>
<th>Not Yet Implemented Functions and Unused Arguments</th>
</tr>
</thead>
</table>

Description

In order to pinpoint missing functionality, the R core team uses these functions for missing R functions and not yet used arguments of existing R functions (which are typically there for compatibility purposes).

You are very welcome to contribute your code ...

Usage

```r
.NotYetImplemented()
.NotYetUsed(arg, error = TRUE)
```

Arguments

- `arg`: an argument of a function that is not yet used.
- `error`: a logical. If TRUE, an error is signalled; if FALSE; only a warning is given.

See Also

the contrary, `Deprecated` and `Defunct` for outdated code.

Examples

```r
require(graphics)
barplot(1:5, inside = TRUE) # 'inside' is not yet used
```

nrow

<table>
<thead>
<tr>
<th>The Number of Rows/Columns of an Array</th>
</tr>
</thead>
</table>

Description

`nrow` and `ncol` return the number of rows or columns present in `x`. `NCOL` and `NROW` do the same treating a vector as 1-column matrix, even a 0-length vector, compatibly with `as.matrix()` or `cbind()`, see the example.

Usage

```r
nrow(x)
ncol(x)
NCOL(x)
NROW(x)
```
Arguments

- **x**: a vector, array, data frame, or **NULL**.

Value

- **an integer** of length 1 or **NULL**, the latter only for `ncol` and `nrow`.

References

See Also

`dim` which returns *all* dimensions, and `length` which gives a number (a 'count') also in cases where `dim()` is NULL, and hence `nrow()` and `ncol()` return NULL; `array`, `matrix`.

Examples

```r
ma <- matrix(1:12, 3, 4)
nrow(ma) # 3
ncol(ma) # 4
ncol(array(1:24, dim = 2:4)) # 3, the second dimension
NCOL(1:12) # 1
NROW(1:12) # 12, the length() of the vector

## as.matrix() produces 1-column matrices from 0-length vectors,
## and so does cbind():
dim(as.matrix(numeric())) # 0 1
dim( cbind(numeric())) # ditto
## consequently, NCOL(.) gives 1, too:
NCOL(numeric()) # 1 and hence
NCOL(NULL) # 1
```

---

**Double Colon and Triple Colon Operators**

Description

Accessing exported and internal variables, i.e. R objects (including lazy loaded data sets) in a namespace.

Usage

```r
pkg::name
pkg:::name
```

Arguments

- **pkg**: package name: symbol or literal character string.
- **name**: variable name: symbol or literal character string.
Details

For a package \texttt{pkg}, \texttt{pkg::name} returns the value of the exported variable \texttt{name} in namespace \texttt{pkg}, whereas \texttt{pkg:::name} returns the value of the internal variable \texttt{name}. The package namespace will be loaded if it was not loaded before the call, but the package will not be attached to the search path. Specifying a variable or package that does not exist is an error.

Note that \texttt{pkg::name} does not access the objects in the environment \texttt{package::pkg} (which does not exist until the package’s namespace is attached); the latter may contain objects not exported from the namespace. It can access datasets made available by lazy-loading.

Note

It is typically a design mistake to use :: in your code since the corresponding object has probably been kept internal for a good reason. Consider contacting the package maintainer if you feel the need to access the object for anything but mere inspection.

See Also

\texttt{get} to access an object masked by another of the same name. \texttt{loadNamespace, asNamespace} for more about namespaces.

Examples

\begin{verbatim}
base::log
base::"+

## Beware -- use ':::' at your own risk! (see "Details")
stats:::coef.default
\end{verbatim}

Description

Packages can supply functions to be called when loaded, attached, detached or unloaded.

Usage

\begin{verbatim}
.onLoad(libname, pkgname)
.onAttach(libname, pkgname)
.onUnload(libpath)
.onDetach(libpath)
.Last.lib(libpath)
\end{verbatim}

Arguments

\begin{itemize}
\item libname a character string giving the library directory where the package defining the namespace was found.
\item pkgname a character string giving the name of the package.
\item libpath a character string giving the complete path to the package.
\end{itemize}
Details

After loading, `loadNamespace` looks for a hook function named `.onLoad` and calls it (with two unnamed arguments) before sealing the namespace and processing exports.

When the package is attached (via `library` or `attachNamespace`), the hook function `.onAttach` is looked for and if found is called (with two unnamed arguments) before the package environment is sealed.

If a function `.onDetach` is in the namespace or `.Last.lib` is exported from the package, it will be called (with a single argument) when the package is detached. Beware that it might be called if `.onAttach` has failed, so it should be written defensively. (It is called within `tryCatch`, so errors will not stop the package being detached.)

If a namespace is unloaded (via `unloadNamespace`), a hook function `.onUnload` is run (with a single argument) before final unloading.

Note that the code in `.onLoad` and `.onUnload` should not assume any package except the base package is on the search path. Objects in the current package will be visible (unless this is circumvented), but objects from other packages should be imported or the double colon operator should be used.

`.onLoad`, `.onUnload`, `.onAttach` and `.onDetach` are looked for as internal objects in the namespace and should not be exported (whereas `.Last.lib` should be).

Note that packages are not detached nor namespaces unloaded at the end of an R session unless the user arranges to do so (e.g., via `.Last`).

Anything needed for the functioning of the namespace should be handled at load/unload times by the `.onLoad` and `.onUnload` hooks. For example, DLLs can be loaded (unless done by a `useDynLib` directive in the ‘NAMESPACE’ file) and initialized in `.onLoad` and unloaded in `.onUnload`. Use `.onAttach` only for actions that are needed only when the package becomes visible to the user (for example a start-up message) or need to be run after the package environment has been created.

Good practice

Loading a namespace should where possible be silent, with startup messages given by `.onAttach`. These messages (and any essential ones from `.onLoad`) should use `packageStartupMessage` so they can be silenced where they would be a distraction.

There should be no calls to `library` nor `require` in these hooks. The way for a package to load other packages is via the ‘Depends’ field in the ‘DESCRIPTION’ file: this ensures that the dependence is documented and packages are loaded in the correct order. Loading a namespace should not change the search path, so rather than attach a package, dependence of a namespace on another package should be achieved by (selectively) importing from the other package’s namespace.

Uses of `library` with argument `help` to display basic information about the package should use `format` on the computed package information object and pass this to `packageStartupMessage`.

There should be no calls to `installed.packages` in startup code: it is potentially very slow and may fail in versions of R before 2.14.2 if package installation is going on in parallel. See its help page for alternatives.

Compiled code should be loaded (e.g., `via library.dynam`) in `.onLoad` or a `useDynLib` directive in the ‘NAMESPACE’ file, and not in `.onAttach`. Similarly, compiled code should not be unloaded (e.g., `via library.dynam.unload`) in `.Last.lib` nor `.onDetach`, only in `.onUnload`.

See Also

`setHook` shows how users can set hooks on the same events, and lists the sequence of events involving all of the hooks.
reg.finalizer for hooks to be run at the end of a session.

loadNamespace for more about namespaces.

---

ns-load

### Loading and Unloading Name Spaces

#### Description

Functions to load and unload name spaces.

#### Usage

- `attachNamespace(ns, pos = 2L, depends = NULL, exclude, include.only)`
- `loadNamespace(package, lib.loc = NULL, keep.source = getOption("keep.source.pkgs"), partial = FALSE, versionCheck = NULL, keep.parse.data = getOption("keep.parse.data.pkgs"))`
- `requireNamespace(package, ..., quietly = FALSE)`
- `loadedNamespaces()`
- `unloadNamespace(ns)`
- `isNamespaceLoaded(name)`

#### Arguments

- **ns**: string or name space object.
- **pos**: integer specifying position to attach.
- **depends**: `NULL` or a character vector of dependencies to be recorded in object .Depends in the package.
- **package**: string naming the package/name space to load.
- **lib.loc**: character vector specifying library search path.
- **keep.source**: Now ignored except during package installation.
- **keep.parse.data**: Ignored except during package installation.
- **partial**: logical; if true, stop just after loading code.
- **versionCheck**: `NULL` or a version specification (a list with components op and version).
- **quietly**: logical: should progress and error messages be suppressed?
- **name**: string or 'name', see `as.symbol`, of a package, e.g., "stats".
- **exclude, include.only**: character vectors; see `library`.
- **...**: further arguments to be passed to `loadNamespace`. 
Details

The functions `loadNamespace` and `attachNamespace` are usually called implicitly when `library` is used to load a name space and any imports needed. However it may be useful at times to call these functions directly.

`loadNamespace` loads the specified name space and registers it in an internal data base. A request to load a name space when one of that name is already loaded has no effect. The arguments have the same meaning as the corresponding arguments to `library`, whose help page explains the details of how a particular installed package comes to be chosen. After loading, `loadNamespace` looks for a hook function named `.onLoad` as an internal variable in the name space (it should not be exported). Partial loading is used to support installation with lazy-loading.

Optionally the package licence is checked during loading: see section `Licenses` in the help for `library`.

`loadNamespace` does not attach the name space it loads to the search path. `attachNamespace` can be used to attach a frame containing the exported values of a name space to the search path (but this is almost always done via `library`). The hook function `.onAttach` is run after the name space exports are attached.

`requireNamespace` is a wrapper for `loadNamespace` analogous to `require` that returns a logical value.

`loadedNamespaces` returns a character vector of the names of the loaded name spaces.

`isNamespaceLoaded(pkg)` is equivalent to but more efficient than `pkg %in% loadedNamespaces()`.

`unloadNamespace` can be used to attempt to force a name space to be unloaded. If the name space is attached, it is first detached, thereby running a `.onDetach` or `.Last.lib` function in the name space if one is exported. An error is signaled and the name space is not unloaded if the name space is imported by other loaded name spaces. If defined, a hook function `.onUnload` is run before removing the name space from the internal registry.

See the comments in the help for `detach` about some issues with unloading and reloading name spaces.

Value

`attachNamespace` returns invisibly the package environment it adds to the search path.

`loadNamespace` returns the name space environment, either one already loaded or the one the function causes to be loaded.

`requireNamespace` returns `TRUE` if it succeeds or `FALSE`.

`loadedNamespaces` returns a `character` vector.

`unloadNamespace` returns `NULL`, invisibly.

See Also

`getNamespace`, `asNamespace`, `topenv`, `.onLoad` (etc); further environment.
Examples

```r
(lns <- loadedNamespaces())
statL <- isNamespaceLoaded("stats")
stopifnot( identical(statL, "stats" %in% lns) )

## The string "foo" and the symbol 'foo' can be used interchangably here:
stopifnot( identical(isNamespaceLoaded("foo"), FALSE),
          identical(isNamespaceLoaded(quote(foo)), FALSE),
          identical(isNamespaceLoaded(quote(stats)), statL))

hasS <- isNamespaceLoaded("splines") # (to restore if needed)
Sns <- asNamespace("splines") # loads it if not already
stopifnot( isNamespaceLoaded("splines"))
unloadNamespace(Sns) # unloading the NS 'object'
stopifnot( ! isNamespaceLoaded("splines"))
if (hasS) loadNamespace("splines") # (restoring previous state)
```

---

**ns-topenv  Top Level Environment**

Description

Finding the top level `environment` from an environment `envir` and its enclosing environments.

Usage

```r
topenv(envir = parent.frame(),
       matchThisEnv = getOption("topLevelEnvironment"))
```

Arguments

- `envir` environment.
- `matchThisEnv` return this environment, if it matches before any other criterion is satisfied. The default, the option `topLevelEnvironment`, is set by `sys.source`, which treats a specific environment as the top level environment. Supplying the argument as NULL or `emptyenv()` means it will never match.

Details

topenv returns the first top level `environment` found when searching `envir` and its enclosing environments. If no top level environment is found, `.GlobalEnv` is returned. An environment is considered top level if it is the internal environment of a namespace, a package environment in the `search` path, or `.GlobalEnv`.

See Also

- `environment`, notably `parent.env()` on “enclosing environments”; `loadNamespace` for more on namespaces.
NULL

Examples

topenv(.GlobalEnv)
topenv(new.env()) # also global env
topenv(environment(ls))# namespace:base
topenv(environment(lm))# namespace:stats

NULL

The Null Object

Description

NULL represents the null object in R: it is a reserved word. NULL is often returned by expressions and functions whose value is undefined.

Usage

NULL
as.null(x, ...)
is.null(x)

Arguments

x an object to be tested or coerced.
... ignored.

Details

NULL can be indexed (see Extract) in just about any syntactically legal way: whether it makes sense or not, the result is always NULL. Objects with value NULL can be changed by replacement operators and will be coerced to the type of the right-hand side.

NULL is also used as the empty pairlist: see the examples. Because pairlists are often promoted to lists, you may encounter NULL being promoted to an empty list.

Objects with value NULL cannot have attributes as there is only one null object: attempts to assign them are either an error (attr) or promote the object to an empty list with attribute(s) (attributes and structure).

Value

as.null ignores its argument and returns NULL.
is.null returns TRUE if its argument’s value is NULL and FALSE otherwise.

Note

is.null is a primitive function.

References

Examples

```r
is.null(list()) # FALSE (on purpose!)
is.null(pairlist()) # TRUE
is.null(integer(0)) # FALSE
is.null(logical(0)) # FALSE
as.null(list(a = 1, b = "c"))
```

### numeric

**Numeric Vectors**

**Description**

Creates or coerces objects of type "numeric". `is.numeric` is a more general test of an object being interpretable as numbers.

**Usage**

```r
numeric(length = 0)
as.numeric(x, ...)
is.numeric(x)
```

**Arguments**

- `length`: A non-negative integer specifying the desired length. Double values will be coerced to integer: supplying an argument of length other than one is an error.
- `x`: object to be coerced or tested.
- `...`: further arguments passed to or from other methods.

**Details**

`numeric` is identical to `double` (and `real`). It creates a double-precision vector of the specified length with each element equal to 0.

`as.numeric` is a generic function, but S3 methods must be written for `as.double`. It is identical to `as.double`.

`is.numeric` is an internal generic primitive function: you can write methods to handle specific classes of objects, see InternalMethods. It is not the same as `is.double`. Factors are handled by the default method, and there are methods for classes "Date", "POSIXt" and "difftime" (all of which return false). Methods for `is.numeric` should only return true if the base type of the class is `double` or `integer` and values can reasonably be regarded as numeric (e.g., arithmetic on them makes sense, and comparison should be done via the base type).

**Value**

For `numeric` and `as.numeric` see `double`.

The default method for `is.numeric` returns TRUE if its argument is of mode "numeric" (type "double" or type "integer") and not a factor, and FALSE otherwise. That is, `is.integer(x) || is.double(x), or (mode(x) == "numeric") && !is.factor(x).`
Warning

If x is a factor, as.numeric will return the underlying numeric (integer) representation, which is often meaningless as it may not correspond to the factor levels, see the ‘Warning’ section in factor (and the 2nd example below).

S4 methods

as.numeric and is.numeric are internally S4 generic and so methods can be set for them via setMethod.

To ensure that as.numeric and as.double remain identical, S4 methods can only be set for as.numeric.

Note on names

It is a historical anomaly that R has two names for its floating-point vectors, double and numeric (and formerly had real).

double is the name of the type. numeric is the name of the mode and also of the implicit class. As an S4 formal class, use “numeric”.

The potential confusion is that R has used mode "numeric" to mean ‘double or integer’, which conflicts with the S4 usage. Thus is.numeric tests the mode, not the class, but as.numeric (which is identical to as.double) coerces to the class.

References

See Also

double, integer, storage.mode.

Examples

## Conversion does trim whitespace; non-numeric strings give NA + warning
as.numeric(c("-.1"," 2.7 ","B"))

## Numeric values are sometimes accidentally converted to factors.
## Converting them back to numeric is trickier than you'd expect.
f <- factor(5:10)
as.numeric(f) # not what you might expect, probably not what you want
## what you typically meant and want:
as.numeric(as.character(f))
## the same, considerably more efficient (for long vectors):
as.numeric(levels(f))[f]
**Description**

How R parses numeric constants.

**Details**

R parses numeric constants in its input in a very similar way to C99 floating-point constants.

Inf and NaN are numeric constants (with typeof(.) "double"). In text input (e.g., in scan and as.double), these are recognized ignoring case as is infinity as an alternative to Inf. NA_real_ and NA_integer_ are constants of types "double" and "integer" representing missing values. All other numeric constants start with a digit or period and are either a decimal or hexadecimal constant optionally followed by L.

Hexadecimal constants start with 0x or 0X followed by a nonempty sequence from 0-9 a-f A-F which is interpreted as a hexadecimal number, optionally followed by a binary exponent. A binary exponent consists of a P or p followed by an optional plus or minus sign followed by a non-empty sequence of (decimal) digits, and indicates multiplication by a power of two. Thus 0x123p456 is 291 × 2^{456}.

Decimal constants consist of a nonempty sequence of digits possibly containing a period (the decimal point), optionally followed by a decimal exponent. A decimal exponent consists of an E or e followed by an optional plus or minus sign followed by a non-empty sequence of digits, and indicates multiplication by a power of ten.

Values which are too large or too small to be representable will overflow to Inf or underflow to 0.0.

A numeric constant immediately followed by i is regarded as an imaginary complex number.

An numeric constant immediately followed by L is regarded as an integer number when possible (and with a warning if it contains a ".").

Only the ASCII digits 0–9 are recognized as digits, even in languages which have other representations of digits. The ‘decimal separator’ is always a period and never a comma.

Note that a leading plus or minus is not regarded by the parser as part of a numeric constant but as a unary operator applied to the constant.

**Note**

When a string is parsed to input a numeric constant, the number may or may not be representable exactly in the C double type used. If not one of the nearest representable numbers will be returned.

R’s own C code is used to convert constants to binary numbers, so the effect can be expected to be the same on all platforms implementing full IEC 600559 arithmetic (the most likely area of difference being the handling of numbers less than .Machine$double.xmin). The same code is used by scan.

**See Also**

Syntax. For complex numbers, see complex. Quotes for the parsing of character constants, Reserved for the “reserved words” in R.
## Examples

```r
## You can create numbers using fixed or scientific formatting.
2.1
2.1e10
-2.1E-10

## The resulting objects have class numeric and type double.
class(2.1)
typeof(2.1)

## This holds even if what you typed looked like an integer.
class(2)
typeof(2)

## If you actually wanted integers, use an "L" suffix.
class(2L)
typeof(2L)

## These are equal but not identical
2 == 2L
identical(2, 2L)

## You can write numbers between 0 and 1 without a leading "0"
## (but typically this makes code harder to read)
.1234

sqrt(1i) # remember elementary math?
utils::str(0xA0)
identical(1L, as.integer(1))

## You can combine the "0x" prefix with the "L" suffix:
identical(0xF, as.integer(15))
```

### numeric_version

#### Numeric Versions

**Description**

A simple S3 class for representing numeric versions including package versions, and associated methods.

**Usage**

```r
numeric_version(x, strict = TRUE)
package_version(x, strict = TRUE)
R_system_version(x, strict = TRUE)
getRversion()
```

**Arguments**

- `x` a character vector with suitable numeric version strings (see ‘Details’); for package_version, alternatively an R version object as obtained by `R.version`.
- `strict` a logical indicating whether invalid numeric versions should results in an error (default) or not.
Details

Numeric versions are sequences of one or more non-negative integers, usually (e.g., in package 'DESCRIPTION' files) represented as character strings with the elements of the sequence concatenated and separated by single '.' or '-' characters. R package versions consist of at least two such integers, an R system version of exactly three (major, minor and patchlevel).

Functions numeric_version, package_version and R_system_version create a representation from such strings (if suitable) which allows for coercion and testing, combination, comparison, summaries (min/max), inclusion in data frames, subscripting, and printing. The classes can hold a vector of such representations.

getRversion returns the version of the running R as an R system version object.

The [[ operator extracts or replaces a single version. To access the integers of a version use two indices: see the examples.

See Also

compareVersion; packageVersion for the version of a specific R package. R.version etc for the version of R (and the information underlying getRversion()).

Examples

```r
x <- package_version(c("1.2-4", "1.2-3", "2.1"))
x < "1.4-2.3"
c(min(x), max(x))
x[2, 2]
x$major
x$minor

if(getRversion() <= "2.5.0") { ## work around missing feature
cat("Your version of R, ", as.character(getRversion()),
   ", is outdated.\n",
   "Now trying to work around that ...\n", sep = "")
}

x[[c(1, 3)]] # '4' as a numeric vector, same as x[1, 3]
x[1, 3] # 4 as an integer
x[[2, 3]] <- 0 # zero the patchlevel
x[[c(2, 3)]] <- 0 # same
x
x[[3]] <- "2.2.3"; x
x <- c(x, package_version("0.0"))
is.na(x)[4] <- TRUE
stopifnot(identical(is.na(x), c(rep(FALSE,3), TRUE)), anyNA(x))
```

octmode

Display Numbers in Octal

Description

Convert or print integers in octal format, with as many digits as are needed to display the largest, using leading zeroes as necessary.
octmode

Usage

as.octmode(x)

## S3 method for class 'octmode'
as.character(x, ...)

## S3 method for class 'octmode'
format(x, width = NULL, ...)

## S3 method for class 'octmode'
print(x, ...)

Arguments

x

An object, for the methods inheriting from class "octmode".

width

NULL or a positive integer specifying the minimum field width to be used, with
padding by leading zeroes.

...

further arguments passed to or from other methods.

Details

Class "octmode" consists of integer vectors with that class attribute, used merely to ensure that they
are printed in octal notation, specifically for Unix-like file permissions such as 755. Subsetting ([) works too.

If width = NULL (the default), the output is padded with leading zeroes to the smallest width needed
for all the non-missing elements.

as.octmode can convert integers (of type "integer" or "double") and character vectors whose
elements contain only digits 0-7 (or are NA) to class "octmode".

There is a ! method and methods for | and &:
these recycle their arguments to the length of the longer and then apply the operators bitwise to each
element.

See Also

These are auxiliary functions for file.info.

hexmode, sprintf for other options in converting integers to octal, strtoi to convert octal strings
to integers.

Examples

(on <- as.octmode(c(16, 32, 127:129))) # "020" "040" "177" "200" "201"
unclass(on[3:4]) # subsetting

## manipulate file modes
fmode <- as.octmode("170")
(fmode | "644") & "755"

umask <- Sys.umask(NA) # depends on platform
c(fmode, "666", "755") & !umask
## on.exit

### Function Exit Code

**Description**

`on.exit` records the expression given as its argument as needing to be executed when the current function exits (either naturally or as the result of an error). This is useful for resetting graphical parameters or performing other cleanup actions.

If no expression is provided, i.e., the call is `on.exit()`, then the current `on.exit` code is removed.

**Usage**

```r
on.exit(expr = NULL, add = FALSE, after = TRUE)
```

**Arguments**

- `expr` an expression to be executed.
- `add` if TRUE, add `expr` to be executed after any previously set expressions (or before if `after` is FALSE); otherwise (the default) `expr` will overwrite any previously set expressions.
- `after` if `add` is TRUE and `after` is FALSE, then `expr` will be added on top of the expressions that were already registered. The resulting last in first out order is useful for freeing or closing resources in reverse order.

**Details**

The `expr` argument passed to `on.exit` is recorded without evaluation. If it is not subsequently removed/replaced by another `on.exit` call in the same function, it is evaluated in the evaluation frame of the function when it exits (including during standard error handling). Thus any functions or variables in the expression will be looked for in the function and its environment at the time of exit: to capture the current value in `expr` use `substitute` or similar.

If multiple `on.exit` expressions are set using `add = TRUE` then all expressions will be run even if one signals an error.

This is a ‘special’ primitive function: it only evaluates the arguments `add` and `after`.

**Value**

Invisible `NULL`.

**References**

**See Also**

`sys.on.exit` which returns the expression stored for use by `on.exit()` in the function in which `sys.on.exit()` is evaluated.
**Examples**

```r
require(graphics)

opar <- par(mai = c(1,1,1,1))
on.exit(par(opar))
```

---

**Description**

Operators for the "Date" class.

There is an Ops method and specific methods for + and - for the Date class.

**Usage**

```r
date + x
x + date
date - x
date1 lop date2
```

**Arguments**

- `date`  
  date objects

- `date1, date2`  
  date objects or character vectors. (Character vectors are converted by as.Date.)

- `x`  
  a numeric vector (in days) or an object of class "difftime", rounded to the nearest whole day.

- `lop`  
  One of `==`, `!=`, `<`, `<=`, `>`, `>=`.

**Details**

- `x` does not need to be integer if specified as a numeric vector, but see the comments about fractional days in the help for Dates.

**Examples**

```r
(z <- Sys.Date())
z + 10
z < c("2009-06-01", "2010-01-01", "2015-01-01")
```
options

Options Settings

Description
Allow the user to set and examine a variety of global options which affect the way in which \( R \) computes and displays its results.

Usage
options(...)
getOption(x, default = NULL)

Arguments
... any options can be defined, using name = value. However, only the ones below are used in base \( R \).
Options can also be passed by giving a single unnamed argument which is a named list.
x a character string holding an option name.
default if the specified option is not set in the options list, this value is returned. This facilitates retrieving an option and checking whether it is set and setting it separately if not.

Details
Invoking options() with no arguments returns a list with the current values of the options. Note that not all options listed below are set initially. To access the value of a single option, one should use, e.g., getOption("width") rather than options("width") which is a list of length one.

Value
For getOption, the current value set for option \( x \), or default (which defaults to NULL) if the option is unset.
For options(), a list of all set options sorted by name. For options(name), a list of length one containing the set value, or NULL if it is unset. For uses setting one or more options, a list with the previous values of the options changed (returned invisibly).

Options used in base \( R \)
add.smooth: typically logical, defaulting to TRUE. Could also be set to an integer for specifying how many (simulated) smooths should be added. This is currently only used by plot.lm.
askYesNo: a function (typically set by a front-end) to ask the user binary response functions in a consistent way, or a vector of strings used by askYesNo to use as default responses for such questions.
browserNLdisabled: logical: whether newline is disabled as a synonym for "n" in the browser.
checkPackageLicense: logical, not set by default. If true, loadNamespace asks a user to accept any non-standard license at first load of the package.

check.bounds: logical, defaulting to FALSE. If true, a warning is produced whenever a vector (atomic or list) is extended, by something like `x <-1:3; x[5]<-6`.

CBoundsCheck: logical, controlling whether `.C` and `.Fortran` make copies to check for array overruns on the atomic vector arguments.

Initially set from value of the environment variable `R_C_BOUNDS_CHECK` (set to yes to enable).

conflicts.policy: character string or list controlling handling of conflicts found in calls to `library` or `require`. See `library` for details.

continue: a non-empty string setting the prompt used for lines which continue over one line.

defaultPackages: the packages that are attached by default when R starts up. Initially set from value of the environment variable `R_DEFAULT_PACKAGES`, or if that is unset to `c("datasets","utils","grDevices","graphics","stats","methods")`. (Set `R_DEFAULT_PACKAGES` to `NULL` or a comma-separated list of package names.) It will not work to set this in a `'.Rprofile'` file, as its value is consulted before that file is read.

deparse.cutoff: integer value controlling the printing of language constructs which are deparsed. Default 60.

deparse.max.lines: controls the number of lines used when deparsing in `browser`, upon entry to a function whose debugging flag is set, and if option traceback.max.lines is unset, of `traceback()`.

Initially unset, and only used if set to a positive integer.

traceback.max.lines: controls the number of lines used when deparsing in `traceback`, if set. Initially unset, and only used if set to a positive integer.

digits: controls the number of significant (see `signif`) digits to print when printing numeric values. It is a suggestion only. Valid values are 1...22 with default 7. See the note in `print.default` about values greater than 15.

digits.secs: controls the maximum number of digits to print when formatting time values in seconds. Valid values are 0...6 with default 0. See `strftime`.

download.file.extra: Extra command-line argument(s) for non-default methods: see `download.file`.

download.file.method: Method to be used for `download.file`. Currently download methods "internal", "wininet" (Windows only), "libcurl", "wget" and "curl" are available. If not set, method = "auto" is chosen: see `download.file`.

echo: logical. Only used in non-interactive mode, when it controls whether input is echoed. Command-line option `--no-echo` sets this to FALSE, but otherwise it starts the session as TRUE.

encoding: The name of an encoding, default "native.enc". See `connections`.

error: either a function or an expression governing the handling of non-catastrophic errors such as those generated by `stop` as well as by signals and internally detected errors. If the option is a function, a call to that function, with no arguments, is generated as the expression. By default the option is not set: see `stop` for the behaviour in that case. The functions `dump.frames` and `recover` provide alternatives that allow post-mortem debugging. Note that these need to be specified as e.g. `options(error = utils::recover)` in startup files such as `'.Rprofile'`.

expressions: sets a limit on the number of nested expressions that will be evaluated. Valid values are 25...500000 with default 5000. If you increase it, you may also want to start R with a larger protection stack; see `--max-ppsize` in `Memory`. Note too that you may cause a segfault from overflow of the C stack, and on OSes where it is possible you may want to increase that. Once the limit is reached an error is thrown. The current number under evaluation can be found by calling `Cstack_info`. 

options

381

checkPackageLicense: logical, not set by default. If true, loadNamespace asks a user to accept any non-standard license at first load of the package.

check.bounds: logical, defaulting to FALSE. If true, a warning is produced whenever a vector (atomic or list) is extended, by something like `x <-1:3; x[5]<-6`.

CBoundsCheck: logical, controlling whether `.C` and `.Fortran` make copies to check for array overruns on the atomic vector arguments.

Initially set from value of the environment variable `R_C_BOUNDS_CHECK` (set to yes to enable).

conflicts.policy: character string or list controlling handling of conflicts found in calls to `library` or `require`. See `library` for details.

continue: a non-empty string setting the prompt used for lines which continue over one line.

defaultPackages: the packages that are attached by default when R starts up. Initially set from value of the environment variable `R_DEFAULT_PACKAGES`, or if that is unset to `c("datasets","utils","grDevices","graphics","stats","methods")`. (Set `R_DEFAULT_PACKAGES` to `NULL` or a comma-separated list of package names.) It will not work to set this in a `'.Rprofile'` file, as its value is consulted before that file is read.

deparse.cutoff: integer value controlling the printing of language constructs which are deparsed. Default 60.

deparse.max.lines: controls the number of lines used when deparsing in `browser`, upon entry to a function whose debugging flag is set, and if option traceback.max.lines is unset, of `traceback()`.

Initially unset, and only used if set to a positive integer.

traceback.max.lines: controls the number of lines used when deparsing in `traceback`, if set. Initially unset, and only used if set to a positive integer.

digits: controls the number of significant (see `signif`) digits to print when printing numeric values. It is a suggestion only. Valid values are 1...22 with default 7. See the note in `print.default` about values greater than 15.

digits.secs: controls the maximum number of digits to print when formatting time values in seconds. Valid values are 0...6 with default 0. See `strftime`.

download.file.extra: Extra command-line argument(s) for non-default methods: see `download.file`.

download.file.method: Method to be used for `download.file`. Currently download methods "internal", "wininet" (Windows only), "libcurl", "wget" and "curl" are available. If not set, method = "auto" is chosen: see `download.file`.

echo: logical. Only used in non-interactive mode, when it controls whether input is echoed. Command-line option `--no-echo` sets this to FALSE, but otherwise it starts the session as TRUE.

encoding: The name of an encoding, default "native.enc". See `connections`.

error: either a function or an expression governing the handling of non-catastrophic errors such as those generated by `stop` as well as by signals and internally detected errors. If the option is a function, a call to that function, with no arguments, is generated as the expression. By default the option is not set: see `stop` for the behaviour in that case. The functions `dump.frames` and `recover` provide alternatives that allow post-mortem debugging. Note that these need to be specified as e.g. `options(error = utils::recover)` in startup files such as `'.Rprofile'`.

expressions: sets a limit on the number of nested expressions that will be evaluated. Valid values are 25...500000 with default 5000. If you increase it, you may also want to start R with a larger protection stack; see `--max-ppsize` in `Memory`. Note too that you may cause a segfault from overflow of the C stack, and on OSes where it is possible you may want to increase that. Once the limit is reached an error is thrown. The current number under evaluation can be found by calling `Cstack_info`. 

interrupt: a function taking no arguments to be called on a user interrupt if the interrupt condition is not otherwise handled.

keep.parse.data: When internally storing source code (keep.source is TRUE), also store parse data. Parse data can then be retrieved with getParseData() and used e.g. for spell checking of string constants or syntax highlighting. The value has effect only when internally storing source code (see keep.source). The default is TRUE.

keep.parse.data.pkgs: As for keep.parse.data, used only when packages are installed. Defaults to FALSE unless the environment variable R_KEEP_PKGPARSE_DATA is set to yes. The space overhead of parse data can be substantial even after compression and it causes performance overhead when loading packages.

keep.source: When TRUE, the source code for functions (newly defined or loaded) is stored internally allowing comments to be kept in the right places. Retrieve the source by printing or using deparse(fn, control = "useSource"). The default is interactive(), i.e., TRUE for interactive use.

keep.source.pkgs: As for keep.source, used only when packages are installed. Defaults to FALSE unless the environment variable R_KEEP_PGSOURCE is set to yes.

matprod: a string selecting the implementation of the matrix products %*%, crossprod, and tcrossprod for double and complex vectors:

- "internal" uses an unoptimized 3-loop algorithm which correctly propagates NaN and Inf values and is consistent in precision with other summation algorithms inside R like sum or colSums (which now means that it uses a long double accumulator for summation if available and enabled, see capabilities).

- "default" uses BLAS to speed up computation, but to ensure correct propagation of NaN and Inf values it uses an unoptimized 3-loop algorithm for inputs that may contain NaN or Inf values. When deemed beneficial for performance, "default" may call the 3-loop algorithm unconditionally, i.e., without checking the input for NaN/Inf values. The 3-loop algorithm uses (only) a double accumulator for summation, which is consistent with the reference BLAS implementation.

- "blas" uses BLAS unconditionally without any checks and should be used with extreme caution. BLAS libraries do not propagate NaN or Inf values correctly and for inputs with NaN/Inf values the results may be undefined.

- "default.simd" is experimental and will likely be removed in future versions of R. It provides the same behavior as "default", but the check whether the input contains NaN/Inf values is faster on some SIMD hardware. On older systems it will run correctly, but may be much slower than "default".

max.print: integer, defaulting to 99999. print or show methods can make use of this option, to limit the amount of information that is printed, to something in the order of (and typically slightly less than) max.print entries.

OutDec: character string containing a single character. The preferred character to be used as the decimal point in output conversions, that is in printing, plotting, format and as.character but not when deparsing nor by sprintf nor formatC (which are sometimes used prior to printing.)

pager: the command used for displaying text files by file.show, details depending on the platform:

- On a unix-alike defaults to ‘R_HOME/bin/pager’, which is a shell script running the command-line specified by the environment variable PAGER whose default is set at configuration, usually to less.

- On Windows defaults to "internal", which uses a pager similar to the GUI console. Another possibility is "console" to use the console itself.
Can be a character string or an \texttt{R} function, in which case it needs to accept the arguments \texttt{(files,header,title,delete.file)} corresponding to the first four arguments of \texttt{file.show}.

\texttt{papersize}: the default paper format used by \texttt{postscript}; set by environment variable \texttt{R_PAPERSIZE} when \texttt{R} is started: if that is unset or invalid it defaults platform dependently

\textbf{on a unix-alike} to a value derived from the locale category \texttt{LC\_PAPER}, or if that is unavailable to a default set when \texttt{R} was built.

\textbf{on Windows} to "a4", or "letter" in US and Canadian locales.

\texttt{PCRE\_limit\_recursion}: Logical: should \texttt{grep(perl = TRUE)} and similar limit the maximal recursion allowed when matching? Only relevant for PCRE1 and PCRE2 <= 10.23.

PCRE can be built not to use a recursion stack (see \texttt{pcre\_config}), but it uses recursion by default with a recursion limit of 10000000 which potentially needs a very large C stack: see the discussion at \url{https://www.pcre.org/original/doc/html/pcrestack.html}. If true, the limit is reduced using \texttt{R}'s estimate of the C stack size available (if known), otherwise 10000. If \texttt{NA}, the limit is imposed only if any input string has 1000 or more bytes. The limit has no effect when PCRE's Just-in-Time compiler is used.

\texttt{PCRE\_study}: Logical or integer: should \texttt{grep(perl = TRUE)} and similar 'study' the patterns? Either logical or a numerical threshold for the minimum number of strings to be matched for the pattern to be studied (the default is 10)). Missing values and negative numbers are treated as false. This option is ignored with PCRE2 (PCRE version >= 10.00) which does not have a separate study phase and patterns are automatically optimized when possible.

\texttt{PCRE\_use\_JIT}: Logical: should \texttt{grep(perl = TRUE)}, \texttt{strsplit(perl = TRUE)} and similar make use of PCRE's Just-In-Time compiler if available? (This applies only to studied patterns with PCRE1.) Default: true. Missing values are treated as false.

\texttt{pdfviewer}: default PDF viewer. The default is set from the environment variable \texttt{R\_PDFVIEWER}, the default value of which

\textbf{on a unix-alike} is set when \texttt{R} is configured, and

\textbf{on Windows} is the full path to open.exe, a utility supplied with \texttt{R}.

\texttt{printcmd}: the command used by \texttt{postscript} for printing; set by environment variable \texttt{R\_PRINTCMD} when \texttt{R} is started. This should be a command that expects either input to be piped to `stdin` or to be given a single filename argument. Usually set to "lpr" on a Unix-alike.

\texttt{prompt}: a non-empty string to be used for \texttt{R}'s prompt; should usually end in a blank (" ").

\texttt{rl\_word\_breaks}: (Unix only:) Used for the readline-based terminal interface. Default value " \\
\t\\n"">=%; |{}\). This is the set of characters use to break the input line into tokens for object- and file-name completion. Those who do not use spaces around operators may prefer " \\
\t\\n"><=%; |{}\)

\texttt{save.defaults, save.image.defaults}: see \texttt{save}.

\texttt{scipen}: integer. A penalty to be applied when deciding to print numeric values in fixed or exponential notation. Positive values bias towards fixed and negative towards scientific notation: fixed notation will be preferred unless it is more than \texttt{scipen} digits wider.

\texttt{setWidthOnResize}: a logical. If set and \texttt{TRUE}, \texttt{R} run in a terminal using a recent \texttt{readline} library will set the width option when the terminal is resized.

\texttt{showWarnCalls, showErrorCalls}: a logical. Should warning and error messages show a summary of the call stack? By default error calls are shown in non-interactive sessions.

\texttt{showNCalls}: integer. Controls how long the sequence of calls must be (in bytes) before ellipses are used. Defaults to 40 and should be at least 30 and no more than 500.
options

show.error.locations: Should source locations of errors be printed? If set to TRUE or "top", the source location that is highest on the stack (the most recent call) will be printed. "bottom" will print the location of the earliest call found on the stack. Integer values can select other entries. The value 0 corresponds to "top" and positive values count down the stack from there. The value -1 corresponds to "bottom" and negative values count up from there.

show.error.messages: a logical. Should error messages be printed? Intended for use with try or a user-installed error handler.

stringsAsFactors: The default setting for default.stringsAsFactors, which in R < 4.1.0 was used to provide the default values of the stringsAsFactors argument of data.frame and read.table.

texi2dvi: used by functions texi2dvi and texi2pdf in package tools.

unix-alike only: Set at startup from the environment variable R_TEXI2DVICMD, which defaults first to the value of environment variable TEXI2DVI, and then to a value set when R was installed (the full path to a texi2dvi script if one was found). If necessary, that environment variable can be set to "emulation".

timeout: positive integer. The timeout for some Internet operations, in seconds. Default 60 (seconds) but can be set from environment variable R_DEFAULT_INTERNET_TIMEOUT. (Invalid values of the option or the variable are silently ignored: non-integer numeric values will be truncated.) See download.file and connections.

toplevelEnvironment: see toopenv and sys.source.

url.method: character string: the default method for url. Normally unset, which is equivalent to "default", which is "internal" except on Windows.

useFancyQuotes: controls the use of directional quotes in sQuote, dQuote and in rendering text help (see Rd2txt in package tools). Can be TRUE, FALSE, "TeX" or "UTF-8".

verbose: logical. Should R report extra information on progress? Set to TRUE by the command-line option '--verbose'.

warn: integer value to set the handling of warning messages. If warn is negative all warnings are ignored. If warn is zero (the default) warnings are stored until the top–level function returns. If 10 or fewer warnings were signalled they will be printed otherwise a message saying how many were signalled. An object called last.warning is created and can be printed through the function warnings. If warn is one, warnings are printed as they occur. If warn is two (or larger, coercible to integer), all warnings are turned into errors.

warnPartialMatchArgs: logical. If true, warns if partial matching is used in argument matching.

warnPartialMatchAttr: logical. If true, warns if partial matching is used in extracting attributes via attr.

warnPartialMatchDollar: logical. If true, warns if partial matching is used for extraction by $.

warning.expression: an R code expression to be called if a warning is generated, replacing the standard message. If non-null it is called irrespective of the value of option warn.

warning.length: sets the truncation limit in bytes for error and warning messages. A non-negative integer, with allowed values 100...8170, default 1000.

nwarnings: the limit for the number of warnings kept when warn = 0, default 50. This will discard messages if called whilst they are being collected. If you increase this limit, be aware that the current implementation pre-allocates the equivalent of a named list for them, i.e., do not increase it to more than say a million.

width: controls the maximum number of columns on a line used in printing vectors, matrices and arrays, and when filling by cat.
Columns are normally the same as characters except in East Asian languages. You may want to change this if you re-size the window that R is running in. Valid values are 10...10000 with default normally 80. (The limits on valid values are in file ‘Print.h’ and can be changed by re-compiling R.) Some R consoles automatically change the value when they are resized.

See the examples on Startup for one way to set this automatically from the terminal width when R is started.

The ‘factory-fresh’ default settings of some of these options are

Others are set from environment variables or are platform-dependent.

**Options set in package grDevices**

These will be set when package grDevices (or its namespace) is loaded if not already set.

- **bitmapType**: (Unix only, incl. macOS) character. The default type for the bitmap devices such as png. Defaults to "cairo" on systems where that is available, or to "quartz" on macOS where that is available.

- **device**: a character string giving the name of a function, or the function object itself, which when called creates a new graphics device of the default type for that session. The value of this option defaults to the normal screen device (e.g., X11, windows or quartz) for an interactive session, and pdf in batch use or if a screen is not available. If set to the name of a device, the device is looked for first from the global environment (that is down the usual search path) and then in the grDevices namespace.

The default values in interactive and non-interactive sessions are configurable via environment variables R_INTERACTIVE_DEVICE and R_DEFAULT_DEVICE respectively.

The search logic for ‘the normal screen device’ is that this is windows on Windows, and quartz if available on macOS (running at the console, and compiled into the build). Otherwise X11 is used if environment variable DISPLAY is set.
device.ask.default: logical. The default for `devAskNewPage("ask")` when a device is opened.

locatorBell: logical. Should selection in locator and identify be confirmed by a bell? Default TRUE. Honoured at least on X11 and windows devices.

windowsTimeout: (Windows-only) integer vector of length 2 representing two times in milliseconds. These control the double-buffering of windows devices when that is enabled: the first is the delay after plotting finishes (default 100) and the second is the update interval during continuous plotting (default 500). The values at the time the device is opened are used.

Other options used by package graphics

max.contour.segments: positive integer, defaulting to 25000 if not set. A limit on the number of segments in a single contour line in `contour` or `contourLines`.

Options set in package stats

These will be set when package `stats` (or its namespace) is loaded if not already set.

contrasts: the default contrasts used in model fitting such as with `aov` or `lm`. A character vector of length two, the first giving the function to be used with unordered factors and the second the function to be used with ordered factors. By default the elements are named `c("unordered","ordered")`, but the names are unused.

na.action: the name of a function for treating missing values (NA’s) for certain situations, see `na.action` and `na.pass`.

show.coef.Pvalues: logical, affecting whether P values are printed in summary tables of coefficients. See `printCoefmat`.

show.nls.convergence: logical, should nls convergence messages be printed for successful fits?

show.signif.stars: logical, should stars be printed on summary tables of coefficients? See `printCoefmat`.

ts.eps: the relative tolerance for certain time series (ts) computations. Default 1e-05.

ts.S.compat: logical. Used to select S compatibility for plotting time-series spectra. See the description of argument log in `plot.spec`.

Options set (or used) in package utils

These will be set (apart from Ncpus) when package `utils` (or its namespace) is loaded if not already set.

browser: The HTML browser to be used by `browseURL`. This sets the default browser on UNIX or a non-default browser on Windows. Alternatively, an R function that is called with a URL as its argument. See `browseURL` for further details.

ccaddress: default Cc: address used by `create.post` (and hence `bug.report` and `help.request`). Can be FALSE or ”".

citation.bibtex.max: default 1; the maximal number of bibentries (bibentry) in a citation for which the bibtex version is printed in addition to the text one.

de.cellwidth: integer: the cell widths (number of characters) to be used in the data editor `dataentry`. If this is unset (the default), 0, negative or NA, variable cell widths are used.
demo.ask: default for the ask argument of demo.

demo.default for the ask argument of demo.

editor: a non-empty character string or an R function that sets the default text editor, e.g., for edit and file.edit. Set from the environment variable EDITOR on UNIX, or if unset VISUAL or vi. As a string it should specify the name of or path to an external command.

demo.default for the ask argument of demo.

example.ask: default for the ask argument of example.

help.ports: optional integer vector for setting ports of the internal HTTP server, see startDynamicHelp.

help.search.types: default types of documentation to be searched by help.search and ??.

help.try.all.packages: default for an argument of help.

help_type: default for an argument of help, used also as the help type by ?.

HTTPUserAgent: string used as the ‘user agent’ in HTTP(S) requests by download.file, url and curlGetHeaders, or NULL when requests will be made without a user agent header. The default is R (\langle{version}\rangle \langle{platform}\rangle \langle{arch}\rangle \langle{os}\rangle) except when ‘libcurl’ is used when it is libcurl/7.\langle{xx}x\rangle.\langle{y}\rangle for the ‘libcurl’ version in use.

install.lock: logical: should per-directory package locking be used by install.packages?

Most useful for binary installs on macOS and Windows, but can be used in a startup file for source installs via R CMD INSTALL. For binary installs, can also be the character string "pkglock".

internet.info: The minimum level of information to be printed on URL downloads etc, using the "internal" and "libcurl" methods. Default is 2, for failure causes. Set to 1 or 0 to get more detailed information (for the "internal" method 0 provides more information than 1).

install.packages.check.source: Used by install.packages (and indirectly update.packages) on platforms which support binary packages. Possible values "yes" and "no", with unset being equivalent to "yes".

install.packages.compile.from.source: Used by install.packages(type = "both") (and indirectly update.packages) on platforms which support binary packages. Possible values are "never", "interactive" (which means ask in interactive use and "never" in batch use) and "always". The default is taken from environment variable R_COMPILE_AND_INSTALL_PACKAGES, with default "interactive" if unset. However, install.packages uses "never" unless a make program is found, consulting the environment variable MAKE.

mailer: default emailing method used by create.post and hence bug.report and help.request.

menu.graphics: Logical: should graphical menus be used if available?. Defaults to TRUE. Currently applies to select.list, chooseCRANmirror, setRepositories and to select from multiple (text) help files in help.

Ncpus: an integer \( n \geq 1 \), used in install.packages as default for the number of cpus to use in a potentially parallel installation, as Ncpus = getOption("Ncpus",1L), i.e., when unset is equivalent to a setting of 1.

pkgType: The default type of packages to be downloaded and installed – see install.packages. Possible values are platform dependently

on Windows "win.binary", "source" and "both" (the default).

on Unix-alikes "source" (the default except under a CRAN macOS build), "mac.binary" and "both" (the default for CRAN macOS builds). ("mac.binary.el-capitan", "mac.binary.mavericks", "mac.binary.leopard" and "mac.binary.universal" are no longer in use.)

Value "binary" is a synonym for the native binary type (if there is one); "both" is used by install.packages to choose between source and binary installs.
repos: URLs of the repositories for use by \texttt{update.packages}. Defaults to \texttt{c(CRAN="@CRAN@")}, a value that causes some utilities to prompt for a CRAN mirror. To avoid this do set the CRAN mirror, by something like \texttt{local({r <-getOption("repos"); r["CRAN"] <-"http://my.local.cran"; options(repos = r))}). Note that you can add more repositories (Bioconductor, R-Forge, Rforge.net ... ) using \texttt{setRepositories}.

SweaveHooks, SweaveSyntax: see \texttt{Sweave}.

unzip: a character string used by \texttt{unzip}: the path of the external program unzip or "internal". Defaults (platform dependently)

\hspace{1em} \textbf{on unix-alikes} to the value of \texttt{R_UNZIPCMD}, which is set in 'etc/Renviron' to the path of the unzip command found during configuration and otherwise to "".

\hspace{1em} \textbf{on Windows} to "internal" when the internal unzip code is used.

\textbf{Options set in package parallel}

These will be set when package \texttt{parallel} (or its namespace) is loaded if not already set.

\textbf{mc.cores}: a integer giving the maximum allowed number of additional R processes allowed to be run in parallel to the current R process. Defaults to the setting of the environment variable \texttt{MC_CORES} if set. Most applications which use this assume a limit of 2 if it is unset.

\textbf{Options used on Unix only}

dvips.cmd: character string giving a command to be used in the (deprecated) off-line printing of help pages via PostScript. Defaults to "dvips".

\textbf{Options used on Windows only}

\textbf{warn.FPU}: logical, by default undefined. If true, a \texttt{warning} is produced whenever \texttt{dyn.load} repairs the control word damaged by a buggy DLL.

\textbf{Note}

For compatibility with S there is a visible object \texttt{.Options} whose value is a pairlist containing the current \texttt{options()} (in no particular order). Assigning to it will make a local copy and not change the original. (\texttt{Using} it however is faster than calling \texttt{options()}).

An option set to \texttt{NULL} is indistinguishable from a non existing option.

\textbf{References}

\textbf{Examples}

\begin{verbatim}
op <- options(); utils::str(op) # op is a named list

getOption("width") == options()$width # the latter needs more memory
options(digits = 15)
pi

# set the editor, and save previous value
old.o <- options(editor = "nedit")
\end{verbatim}
```r
order

## OLD OPTIONS
options(check.bounds = TRUE, warn = 1)
x <- NULL; x[4] <- "yes" # gives a warning

options(digits = 5)
print(1e5)
options(scipen = 3): print(1e5)

options(op)    # reset (all) initial options
options("digits")

## Not run: ## set contrast handling to be like S
options(contrasts = c("contr.helmert", "contr.poly"))

## End(Not run)

## Not run: ## on error, terminate the R session with error status 66
options(error = quote(q("no", status = 66, runLast = FALSE)))
stop("test it")

## End(Not run)

## Not run: ## Set error actions for debugging:
## enter browser on error, see ?recover:
options(error = recover)
## allows to call debugger() afterwards, see ?debugger:
options(error = dump.frames)
## A possible setting for non-interactive sessions
options(error = quote((dump.frames(to.file = TRUE); q())))

## End(Not run)

# Compare the two ways to get an option and use it
# accounting for the possibility it might not be set.
if(as.logical(getOption("performCleanp", TRUE)))
cat("do cleanup\n")

## Not run:
# a clumsier way of expressing the above w/o the default.
tmp <- getOption("performCleanup")
if(is.null(tmp))
tmp <- TRUE
if(tmp)
cat("do cleanup\n")

## End(Not run)

---

**order**

### Ordering Permutation

**Description**

order returns a permutation which rearranges its first argument into ascending or descending order,
breaking ties by further arguments. sort.list does the same, using only one argument. See the examples for how to use these functions to sort data frames, etc.

Usage

```r
order(..., na.last = TRUE, decreasing = FALSE,  
     method = c("auto", "shell", "radix"))
```

```r
sort.list(x, partial = NULL, na.last = TRUE, decreasing = FALSE,  
          method = c("auto", "shell", "quick", "radix"))
```

Arguments

`...` a sequence of numeric, complex, character or logical vectors, all of the same length, or a classed R object.

`x` an atomic vector for methods "shell" and "quick". When `x` is a non-atomic R object, the default "auto" and "radix" methods may work if `order(x,..)` does.

`partial` vector of indices for partial sorting. (Non-NULL values are not implemented.)

`decreasing` logical. Should the sort order be increasing or decreasing? For the "radix" method, this can be a vector of length equal to the number of arguments in .... For the other methods, it must be length one.

`na.last` for controlling the treatment of NAs. If TRUE, missing values in the data are put last; if FALSE, they are put first; if NA, they are removed (see ‘Note’.)

`method` the method to be used: partial matches are allowed. The default ("auto") implies "radix" for short numeric vectors, integer vectors, logical vectors and factors. Otherwise, it implies "shell". For details of methods "shell", "quick", and "radix", see the help for `sort`.

Details

In the case of ties in the first vector, values in the second are used to break the ties. If the values are still tied, values in the later arguments are used to break the tie (see the first example). The sort used is stable (except for method = "quick"), so any unresolved ties will be left in their original ordering.

Complex values are sorted first by the real part, then the imaginary part.

Except for method "radix", the sort order for character vectors will depend on the collating sequence of the locale in use: see `Comparison`.

The "shell" method is generally the safest bet and is the default method, except for short factors, numeric vectors, integer vectors and logical vectors, where "radix" is assumed. Method "radix" stably sorts logical, numeric and character vectors in linear time. It outperforms the other methods, although there are caveats (see `sort`). Method "quick" for `sort.list` is only supported for numeric `x` with `na.last = NA`, is not stable, and is slower than "radix".

`partial = NULL` is supported for compatibility with other implementations of S, but no other values are accepted and ordering is always complete.

For a classed R object, the sort order is taken from `xtfrm`: as its help page notes, this can be slow unless a suitable method has been defined or `is.numeric(x)` is true. For factors, this sorts on the internal codes, which is particularly appropriate for ordered factors.
Value

An integer vector unless any of the inputs has $2^{31}$ or more elements, when it is a double vector.

Warning

In programmatic use it is unsafe to name the ... arguments, as the names could match current or future control arguments such as decreasing. A sometimes-encountered unsafe practice is to call do.call('order',df_obj) where df_obj might be a data frame: copy df_obj and remove any names, for example using unname.

Note

sort.list can get called by mistake as a method for sort with a list argument: it gives a suitable error message for list x.

There is a historical difference in behaviour for na.last = NA: sort.list removes the NAs and then computes the order amongst the remaining elements: order computes the order amongst the non-NA elements of the original vector. Thus

```r
x[order(x, na.last = NA)]
zz <- x[!is.na(x)]; zz[sort.list(x, na.last = NA)]
```

both sort the non-NA values of x.

Prior to R 3.3.0 method = "radix" was only supported for integers of range less than 100,000.

sort, rank, xtfrm.

Examples

```r
require(stats)
(ii <- order(x <- c(1,1,3:1,1:4,3), y <- c(9,9:1), z <- c(2,1:9)))
## 6 5 2 1 7 4 10 8 3 9
rbind(x, y, z)[,ii] # shows the reordering (ties via 2nd & 3rd arg)
```

```r
## Suppose we wanted descending order on y.
## A simple solution for numeric 'y' is
rbind(x, y, z)[, order(x, -y, z)]
## More generally we can make use of xtfrm
cy <- as.character(y)
rbind(x, y, z)[, order(x, -xtfrm(cy), z)]
## The radix sort supports multiple 'decreasing' values:
rbind(x, y, z)[, order(x, cy, z, decreasing = c(FALSE, TRUE, FALSE),
method="radix")]
```

```r
## Sorting data frames:
```
dd <- transform(data.frame(x, y, z), 
    z = factor(z, labels = LETTERS[9:1]))
## Either as above (for factor 'z': using internal coding):
## or along 1st column, ties along 2nd, ... *arbitrary* no. columns:
dd[ do.call(order, dd), ]

set.seed(1) # reproducible example:
d4 <- data.frame(x = round(rnorm(100)), y = round(10*runif(100)),
                 z = round(8*rnorm(100)), u = round(50*runif(100)))
(d4s <- d4[ do.call(order, d4), ])
(i <- which(diff(d4s[, 3]) == 0))
## in 2 places, needed 3 cols to break ties:
d4s[ rbind(i, i+1), ]

## rearrange matched vectors so that the first is in ascending order
x <- c(5:1, 6:8, 12:9)
y <- (x - 5)^2
o <- order(x)
rbind(x[o], y[o])

## tests of na.last
a <- c(4, 3, 2, NA, 1)
b <- c(4, NA, 2, 7, 1)
z <- cbind(a, b)
(o <- order(a, b)); z[o, ]
(o <- order(a, b, na.last = FALSE)); z[o, ]
(o <- order(a, b, na.last = NA)); z[o, ]

## speed examples on an average laptop for long vectors:
## factor/small-valued integers:
x <- factor(sample(letters, 1e7, replace = TRUE))
system.time(o <- sort.list(x, method = "quick", na.last = NA)) # 0.1 sec
stopifnot(!is.unsorted(x[o]))
system.time(o <- sort.list(x, method = "radix")) # 0.05 sec, 2X faster
stopifnot(!is.unsorted(x[o]))
## large-valued integers:
xx <- sample(1:200000, 1e7, replace = TRUE)
system.time(o <- sort.list(xx, method = "quick", na.last = NA)) # 0.3 sec
system.time(o <- sort.list(xx, method = "radix")) # 0.2 sec
## character vectors:
xx <- sample(state.name, 1e6, replace = TRUE)
system.time(o <- sort.list(xx, method = "shell")) # 2 sec
system.time(o <- sort.list(xx, method = "radix")) # 0.007 sec, 300X faster
## double vectors:
xx <- rnorm(1e6)
system.time(o <- sort.list(xx, method = "shell")) # 0.4 sec
system.time(o <- sort.list(xx, method = "quick", na.last = NA)) # 0.1 sec
system.time(o <- sort.list(xx, method = "radix")) # 0.05 sec, 2X faster

outer

Outer Product of Arrays
Description
The outer product of the arrays X and Y is the array A with dimension c(dim(X), dim(Y)) where element A[c(arrayindex.x, arrayindex.y)] = FUN(X[arrayindex.x], Y[arrayindex.y], ...).

Usage
outer(X, Y, FUN = "*", ...) 
X %o% Y

Arguments
X, Y
First and second arguments for function FUN. Typically a vector or array.
FUN
a function to use on the outer products, found via match.fun (except for the special case "*").
...
optional arguments to be passed to FUN.

Details
X and Y must be suitable arguments for FUN. Each will be extended by rep to length the products of the lengths of X and Y before FUN is called.
FUN is called with these two extended vectors as arguments (plus any arguments in ...). It must be a vectorized function (or the name of one) expecting at least two arguments and returning a value with the same length as the first (and the second).
Where they exist, the [dim]names of X and Y will be copied to the answer, and a dimension assigned which is the concatenation of the dimensions of X and Y (or lengths if dimensions do not exist).
FUN = "*" is handled as a special case via as.vector(X) %*% t(as.vector(Y)), and is intended only for numeric vectors and arrays.
%o% is binary operator providing a wrapper for outer(x, y, ")

**Parentheses and Braces**

**Description**

Open parenthesis, (, and open brace, {, are *Primitive* functions in R.

Effectively, ( is semantically equivalent to the identity function(x) x, whereas { is slightly more interesting, see examples.

**Usage**

```
( ... )
{ ... }
```

**Value**

For (, the result of evaluating the argument. This has visibility set, so will auto-print if used at top-level.

For {, the result of the last expression evaluated. This has the visibility of the last evaluation.

**References**

**See Also**

`if, return`, etc for other objects used in the R language itself.

`Syntax` for operator precedence.

**Examples**

```
f <- get(")
e <- expression(3 + 2 * 4)
identical(f(e), e)

do <- get("{

do(x <- 3, y <- 2*x-3, 6-x-y); x; y

## note the differences
(2+3)
{2+3; 4+5}
(invisible(2+3))
{invisible(2+3)}
```
parse | Parse R Expressions

Description

parse() returns the parsed but unevaluated expressions in an expression, a "list" of calls.
str2expression(s) and str2lang(s) return special versions of parse(text=s,keep.source=FALSE) and can therefore be regarded as transforming character strings s to expressions, calls, etc.

Usage

parse(file = "", n = NULL, text = NULL, prompt = "?",
      keep.source = getOption("keep.source"), srcfile,
      encoding = "unknown")

str2lang(s)
str2expression(text)

Arguments

file a connection, or a character string giving the name of a file or a URL to read the expressions from. If file is "" and text is missing or NULL then input is taken from the console.
n integer (or coerced to integer). The maximum number of expressions to parse. If n is NULL or negative or NA the input is parsed in its entirety.
text character vector. The text to parse. Elements are treated as if they were lines of a file. Other R objects will be coerced to character if possible.
prompt the prompt to print when parsing from the keyboard. NULL means to use R’s prompt, getOption(“prompt”).
keep.source a logical value; if TRUE, keep source reference information.
srcfile NULL, a character vector, or a srcfile object. See the ‘Details’ section.
encoding encoding to be assumed for input strings. If the value is "latin1" or "UTF-8" it is used to mark character strings as known to be in Latin-1 or UTF-8: it is not used to re-encode the input. To do the latter, specify the encoding as part of the connection con or via options(encoding=): see the example under file.
s a character vector of length 1, i.e., a “string”.

Details

parse(....): If text has length greater than zero (after coercion) it is used in preference to file.
All versions of R accept input from a connection with end of line marked by LF (as used on Unix), CRLF (as used on DOS/Windows) or CR (as used on classic Mac OS). The final line can be incomplete, that is missing the final EOL marker.
When input is taken from the console, n = NULL is equivalent to n = 1, and n < 0 will read until an EOF character is read. (The EOF character is Ctrl-Z for the Windows front-ends.) The
The default for srcfile is set as follows. If keep.source is not TRUE, srcfile defaults to a character string, either "<text>" or one derived from file. When keep.source is TRUE, if text is used, srcfile will be set to a srcfilecopy containing the text. If a character string is used for file, a srcfile object referring to that file will be used.

When srcfile is a character string, error messages will include the name, but source reference information will not be added to the result. When srcfile is a srcfile object, source reference information will be retained.

str2expression(s): for a character vector s, str2expression(s) corresponds to parse(text = s, keep.source = FALSE), which is always of type (typeof) and class expression.

str2lang(s): for a character string s, str2lang(s) corresponds to parse(text = s, keep.source = FALSE)[[1]] (plus a check that both s and the parse(*) result are of length one) which is typically a call but may also be a symbol aka name, NULL or an atomic constant such as 2, 1L, or TRUE. Put differently, the value of str2lang(.) is a call or one of its parts, in short "a call or simpler".

Currently, encoding is not handled in str2lang() and str2expression().

Value

parse() and str2expression() return an object of type "expression", for parse() with up to n elements if specified as a non-negative integer.

str2lang(s), s a string, returns "a call or simpler", see the ‘Details:’ section.

When srcfile is non-NULL, a "srcref" attribute will be attached to the result containing a list of srcref records corresponding to each element, a "srcfile" attribute will be attached containing a copy of srcfile, and a "wholeSrcref" attribute will be attached containing a srcref record corresponding to all of the parsed text. Detailed parse information will be stored in the "srcfile" attribute, to be retrieved by getParseData.

A syntax error (including an incomplete expression) will throw an error.

Character strings in the result will have a declared encoding if encoding is "latin1" or "UTF-8", or if text is supplied with every element of known encoding in a Latin-1 or UTF-8 locale.

Partial parsing

When a syntax error occurs during parsing, parse signals an error. The partial parse data will be stored in the srcfile argument if it is a srcfile object and the text argument was used to supply the text. In other cases it will be lost when the error is triggered.

The partial parse data can be retrieved using getParseData applied to the srcfile object. Because parsing was incomplete, it will typically include references to "parent" entries that are not present.

Note

Using parse(text = *, ...) or its simplified and hence more efficient versions str2lang() or str2expression() is at least an order of magnitude less efficient than call(...) or as.call().

References

See Also

`scan`, `source`, `eval`, `deparse`.

The source reference information can be used for debugging (see e.g. `setBreakpoint`) and profiling (see `Rprof`). It can be examined by `getSrcref` and related functions. More detailed information is available through `getParseData`.

Examples

```r
fil <- tempfile(fileext = "Rdmped")
cat("x <- c(1, 4)\n x ^ 3 -10 ; outer(1:7, 5:9)\n", file = fil)
# parse 3 statements from our temp file
parse(file = fil, n = 3)
unlink(fil)

## str2lang(<string>) || str2expression(<character>) :
stopifnot(exprs = {
  identical( str2lang("log(y)"), quote(log(y)) )
  identical( str2lang("abc" ), quote(abc) -> qa)
  is.symbol(qa) & !is.call(qa) # a symbol/name, not a call
  identical( str2lang("1.375" ), 1.375) # just a number, not a call
  identical( str2expression(c("# a comment", "", "42")), expression(42) )
})

# A partial parse with a syntax error
txt <- "x <- 1
an error"

sf <- srcfile("txt")
try(parse(text = txt, srcfile = sf))
getParseData(sf)
```

---

### paste

**Concatenate Strings**

**Description**

Concatenate vectors after converting to character.

**Usage**

```r
paste (... , sep = " ", collapse = NULL, recycle0 = FALSE)
paste0(... , collapse = NULL, recycle0 = FALSE)
```
Arguments

... one or more R objects, to be converted to character vectors.

sep a character string to separate the terms. Not NA_character_.

collapse an optional character string to separate the results. Not NA_character_.

recycle0 logical indicating if zero-length character arguments should lead to the zero-length character(0) after the sep-phase (which turns into "" in the collapse-phase, i.e., when collapse is not NULL).

Details

paste converts its arguments (via as.character) to character strings, and concatenates them (separating them by the string given by sep). If the arguments are vectors, they are concatenated term-by-term to give a character vector result. Vector arguments are recycled as needed, with zero-length arguments being recycled to "" only if recycle0 is not true or collapse is not NULL.

Note that paste() coerces NA_character_, the character missing value, to "NA" which may seem undesirable, e.g., when pasting two character vectors, or very desirable, e.g. in paste("the value of p is ",p).

paste0(...,collapse) is equivalent to paste(...,sep = "",collapse), slightly more efficiently.

If a value is specified for collapse, the values in the result are then concatenated into a single string, with the elements being separated by the value of collapse.

Value

A character vector of the concatenated values. This will be of length zero if all the objects are, unless collapse is non-NULL, in which case it is "" (a single empty string).

If any input into an element of the result is in UTF-8 (and none are declared with encoding "bytes", see Encoding), that element will be in UTF-8, otherwise in the current encoding in which case the encoding of the element is declared if the current locale is either Latin-1 or UTF-8, at least one of the corresponding inputs (including separators) had a declared encoding and all inputs were either ASCII or declared.

If an input into an element is declared with encoding "bytes", no translation will be done of any of the elements and the resulting element will have encoding "bytes". If collapse is non-NULL, this applies also to the second, collapsing, phase, but some translation may have been done in pasting object together in the first phase.

References

See Also

toString typically calls paste(*,collapse="","). String manipulation with as.character, substr, nchar, strsplit; further, cat which concatenates and writes to a file, and sprintf for C like string construction.

'plotmath' for the use of paste in plot annotation.
Examples

```r
## When passing a single vector, paste0 and paste work like as.character.
paste0(1:12)
paste(1:12)  # same
as.character(1:12)  # same

## If you pass several vectors to paste0, they are concatenated in a
## vectorized way.
(nth <- paste0(1:12, c("st", "nd", "rd", rep("th", 9))))

## paste works the same, but separates each input with a space.
## Notice that the recycling rules make every input as long as the longest input.
paste(month.abb, "is the", nth, "month of the year.")
paste(month.abb, letters)

## You can change the separator by passing a sep argument
## which can be multiple characters.
paste(month.abb, "is the", nth, "month of the year.", sep = ".")

## To collapse the output into a single string, pass a collapse argument.
paste0(nth, collapse = ",")

## For inputs of length 1, use the sep argument rather than collapse
paste("1st", "2nd", "3rd", collapse = ",")  # probably not what you wanted
paste("1st", "2nd", "3rd", sep = ",")

## You can combine the sep and collapse arguments together.
paste(month.abb, nth, sep = ":", collapse = ";")

## Using paste() in combination with strwrap() can be useful
## for dealing with long strings.
(title <- paste(strwrap(
  "Stopping distance of cars (ft) vs. speed (mph) from Ezekiel (1930)",
  width = 30), collapse = "\n"))
plot(dist ~ speed, cars, main = title)

## 'recycle0 = TRUE' allows more vectorized behaviour, i.e. zero-length recycling:
valid <- FALSE
val <- pi
paste("The value is", val[valid], "-- not so good!")
paste("The value is", val[valid], "-- good: empty!", recycle0=TRUE)  # -> character(0)

## When 'collapse = <string>', the result is a length-1 string:
paste("foo", (), "bar", collapse="|")  # |--> "foo bar"
paste("foo", (), "bar", collapse="|", recycle0 = TRUE)  # |--> ""

## all empty args
paste( collapse="|")  # |--> "" as do all these:
paste( collapse="|", recycle0 = TRUE)
paste([], collapse="|")
paste([], collapse="|", recycle0 = TRUE)
```

---

**path.expand**

*Expand File Paths*
Description

Expand a path name, for example by replacing a leading tilde by the user's home directory (if defined on that platform).

Usage

path.expand(path)

Arguments

path character vector containing one or more path names.

Details

(These details are for a Unix-alike: the details differ on Windows.)

On most builds of R a leading ~user will expand to the home directory of user (since R 4.1.0 also without readline in use).

There are possibly different concepts of ‘home directory’: that usually used is the setting of the environment variable HOME.

The ‘path names’ need not exist nor be valid path names but they do need to be representable in the session encoding.

Value

A character vector of possibly expanded path names: where the home directory is unknown or none is specified the path is returned unchanged.

See Also

basename, normalizePath.

Examples

path.expand("~/foo")

pcre_config

Report Configuration Options for PCRE

Description

Report some of the configuration options of the version of PCRE in use in this R session.

Usage

pcre_config()
**pipeOp**

**Value**
A named logical vector, currently with elements

**UTF-8** Support for UTF-8 inputs. Required.

**Unicode properties**
Support for \p{xx} and \P{xx} in regular expressions. Desirable and used by some CRAN packages. As of PCRE2, always present with support for UTF-8.

**JIT** Support for just-in-time compilation. Desirable for speed (but only available as a compile-time option on certain architectures).

**stack** Does match recursion use a stack (TRUE, the default for PCRE1 and PCRE2 older than 10.30) or a heap? See the discussion at [https://www.pcre.org/original/doc/html/pcrestack.html](https://www.pcre.org/original/doc/html/pcrestack.html) (Added in R 3.4.0.). No longer relevant and always FALSE in PCRE2 since version 10.30 which no longer uses function recursion to remember backtracking positions.

**See Also**
- `extSoftVersion` for the PCRE version.

**Examples**
```r
pcre_config()
```

---

**pipeOp**

**Pipe Operator**

**Description**
Pipe a value into a call expression or a function.

**Usage**

```r
1hs |> rhs
```

**Arguments**

- **1hs** expression producing a value.
- **rhs** a call expression or a function expression.

**Details**
A pipe expression passes, or pipes, the result of the 1hs expression to the rhs expression.

If the rhs expression is a call, then the 1hs is inserted as the first argument in the call. So \( x |> f(y) \) is interpreted as \( f(x, y) \). To avoid ambiguities, functions in 1hs calls may not be syntactically special, such as + or if.

If the rhs expression is a function expression, then the function is called with the 1hs value as its argument. This is useful when the 1hs needs to be passed as an argument other than the first in the rhs call. See the lm example below.
Pipe notation allows a nested sequence of calls to be written in a way that may make the sequence of processing steps easier to follow.

Currently, pipe operations are implemented as syntax transformations. So an expression written as \( x \mid> f(y) \) is parsed as \( f(x, y) \).

**Value**

Returns the result of evaluating the transformed expression.

**Note**

Pipe support is experimental and may change prior to release.

**See Also**

The pipe operator is motivated by the pipe introduced in the **magrittr** package, but more streamlined. It is similar to pipe or pipeline operators introduced in other languages, including Julia and JavaScript.

**Examples**

# simple uses:
mtcars |> head()
mtcars |> head(2)
mtcars |> subset(cyl == 4) |> nrow()

# passing the lhs into an argument other than the first:
mtcars |> subset(cyl == 4) |> function(d) lm(mpg ~ disp, data = d)
mtcars |> subset(cyl == 4) |> \( \lambda(d) \) lm(mpg ~ disp, data = d)

# the pipe operator is implemented as a syntax transformation:
quote(mtcars |> subset(cyl == 4) |> nrow())
quote(x |> function(x) x + 1)

---

**plot**

*Generic X-Y Plotting*

**Description**

Generic function for plotting of R objects.

For simple scatter plots, `plot.default` will be used. However, there are `plot` methods for many R objects, including `functions`, `data.frames`, `density` objects, etc. Use `methods(plot)` and the documentation for these. Most of these methods are implemented using traditional graphics (the `graphics` package), but this is not mandatory.

For more details about graphical parameter arguments used by traditional graphics, see `par`.

**Usage**

`plot(x, y, ...)`
Arguments

\(x\) the coordinates of points in the plot. Alternatively, a single plotting structure, function or any \(R\) object with a plot method can be provided.

\(y\) the y coordinates of points in the plot, optional if \(x\) is an appropriate structure.

\(\ldots\) Arguments to be passed to methods, such as graphical parameters (see \texttt{par}). Many methods will accept the following arguments:

- \texttt{type} what type of plot should be drawn. Possible types are
  - "p" for points,
  - "l" for lines,
  - "b" for both,
  - "c" for the lines part alone of "b",
  - "o" for both ‘overplotted’.
  - "h" for ‘histogram’ like (or ‘high-density’) vertical lines,
  - "s" for stair steps,
  - "S" for other steps, see ‘Details’ below,
  - "n" for no plotting.

All other types give a warning or an error; using, e.g., \texttt{type = "punkte"} being equivalent to \texttt{type = "p"} for \(S\) compatibility. Note that some methods, e.g. \texttt{plot.factor}, do not accept this.

- \texttt{main} an overall title for the plot: see \texttt{title}.
- \texttt{sub} a sub title for the plot: see \texttt{title}.
- \texttt{xlab} a title for the x axis: see \texttt{title}.
- \texttt{ylab} a title for the y axis: see \texttt{title}.
- \texttt{asp} the y/x aspect ratio, see \texttt{plot.window}.

Details

The two step types differ in their x-y preference: Going from \((x_1, y_1)\) to \((x_2, y_2)\) with \(x_1 < x_2\), type = "s" moves first horizontal, then vertical, whereas type = "S" moves the other way around.

Note

The \texttt{plot} generic was moved from the \texttt{graphics} package to the \texttt{base} package in \(R\) 4.0.0. It is currently re-exported from the \texttt{graphics} namespace to allow packages importing it from there to continue working, but this may change in future versions of \(R\).

See Also

\texttt{plot.default}, \texttt{plot.formula} and other methods: \texttt{points}, \texttt{lines}, \texttt{par}. For thousands of points, consider using \texttt{smoothScatter()} instead of \texttt{plot()}.

For X-Y-Z plotting see \texttt{contour}, \texttt{persp} and \texttt{image}.

Examples

```r
require(stats) # for lowess, rpois, rnorm
require(graphics) # for plot methods
plot(cars)
lines(lowess(cars))
plot(sin, -pi, 2*pi) # see ?plot.function
```
pmatch

Partial String Matching

Description

pmatch seeks matches for the elements of its first argument among those of its second.

Usage

pmatch(x, table, nomatch = NA_integer_, duplicates.ok = FALSE)

Arguments

x

the values to be matched: converted to a character vector by as.character. Long vectors are supported.

table

the values to be matched against: converted to a character vector. Long vectors are not supported.

nomatch

the value to be returned at non-matching or multiply partially matching positions. Note that it is coerced to integer.

duplicates.ok

should elements be in table be used more than once?

Details

The behaviour differs by the value of duplicates.ok. Consider first the case if this is true. First exact matches are considered, and the positions of the first exact matches are recorded. Then unique partial matches are considered, and if found recorded. (A partial match occurs if the whole of the element of x matches the beginning of the element of table.) Finally, all remaining elements of x are regarded as unmatched. In addition, an empty string can match nothing, not even an exact match to an empty string. This is the appropriate behaviour for partial matching of character indices, for example.

If duplicates.ok is FALSE, values of table once matched are excluded from the search for subsequent matches. This behaviour is equivalent to the R algorithm for argument matching, except for the consideration of empty strings (which in argument matching are matched after exact and partial matching to any remaining arguments).

ccharmacht is similar to pmatch with duplicates.ok true, the differences being that it differentiates between no match and an ambiguous partial match, it does match empty strings, and it does not allow multiple exact matches.

NA values are treated as if they were the string constant "NA".
Value

An integer vector (possibly including NA if nomatch = NA) of the same length as x, giving the indices of the elements in table which matched, or nomatch.

References

See Also

match, champmatch and match.arg, match.fun, match.call, for function argument matching etc.,
startsWith for particular checking of initial matches; grep etc for more general (regexp) matching of strings.

Examples

```r
pmatch("", "")  # returns NA
pmatch("m", c("mean", "median", "mode"))  # returns NA
pmatch("med", c("mean", "median", "mode"))  # returns 2

pmatch(c("", "ab", "ab"), c("abc", "ab"), dup = FALSE)
pmatch(c("", "ab", "ab"), c("abc", "ab"), dup = TRUE)  # compare
charmatch(c("", "ab", "ab"), c("abc", "ab"))
```

polyroot

Find Zeros of a Real or Complex Polynomial

Description

Find zeros of a real or complex polynomial.

Usage

```r
polyroot(z)
```

Arguments

z the vector of polynomial coefficients in increasing order.

Details

A polynomial of degree \( n - 1 \),

\[
p(x) = z_1 + z_2 x + \cdots + z_n x^{n-1}
\]

is given by its coefficient vector \( z[1:n] \). \texttt{polyroot} returns the \( n - 1 \) complex zeros of \( p(x) \) using the Jenkins-Traub algorithm.

If the coefficient vector \( z \) has zeroes for the highest powers, these are discarded.

There is no maximum degree, but numerical stability may be an issue for all but low-degree polynomials.
Value
A complex vector of length \( n - 1 \), where \( n \) is the position of the largest non-zero element of \( z \).

Source
C translation by Ross Ihaka of Fortran code in the reference, with modifications by the R Core Team.

References

See Also
uniroot for numerical root finding of arbitrary functions; complex and the zero example in the demos directory.

Examples
```
polyroot(c(1, 2, 1))
round(polyroot(choose(8, 0:8)), 11) # guess what!
for (n1 in 1:4) print(polyroot(1:n1), digits = 4)
polyroot(c(1, 2, 1, 0, 0)) # same as the first
```

---

**pos.to.env**

Convert Positions in the Search Path to Environments

Description
Returns the environment at a specified position in the search path.

Usage
```
pos.to.env(x)
```

Arguments

\( x \)

an integer between 1 and \( \text{length(search())} \), the length of the search path, or -1.

Details
Several R functions for manipulating objects in environments (such as get and ls) allow specifying environments via corresponding positions in the search path. pos.to.env is a convenience function for programmers which converts these positions to corresponding environments; users will typically have no need for it. It is primitive.

-1 is interpreted as the environment the function is called from.

This is a primitive function.
Examples

pos.to.env(1) # R_GlobalEnv
# the next returns the base environment
pos.to.env(length(search()))

pretty Pretty Breakpoints

Description

Compute a sequence of about \(n+1\) equally spaced ‘round’ values which cover the range of the values in \(x\). The values are chosen so that they are 1, 2 or 5 times a power of 10.

Usage

pretty(x, ...)

## Default S3 method:
pretty(x, n = 5, min.n = n %/% 3, shrink.sml = 0.75,
high.u.bias = 1.5, u5.bias = .5 + 1.5*high.u.bias,
eps.correct = 0, ...)

Arguments

x an object coercible to numeric by \code{as.numeric}.
n integer giving the desired number of intervals. Non-integer values are rounded down.
min.n nonnegative integer giving the minimal number of intervals. If \(\text{min.n} == 0\), pretty(.) may return a single value.
shrink.sml positive number, a factor (smaller than one) by which a default scale is shrunk in the case when range(\(x\)) is very small (usually 0).
high.u.bias non-negative numeric, typically > 1. The interval unit is determined as \{1,2,5,10\} times \(b\), a power of 10. Larger high.u.bias values favor larger units.
u5.bias non-negative numeric multiplier favoring factor 5 over 2. Default and ‘optimal’: \(u5.b >= 0.5 + 1.5*\text{high.u.bias}\).
eps.correct integer code, one of \{0,1,2\}. If non-0, an epsilon correction is made at the boundaries such that the result boundaries will be outside range(\(x\)); in the small case, the correction is only done if \(\text{eps.correct} >= 2\).
...

Details

pretty ignores non-finite values in \(x\).

Let \(d \leftarrow \max(x) - \min(x) \geq 0\). If \(d\) is not (very close) to 0, we let \(c \leftarrow d/n\), otherwise more or less \(c \leftarrow \max(\text{abs}(\text{range}(x)))*\text{shrink.sml}/\text{min.n}\). Then, the 10 base \(b\) is \(10^\left\lfloor \log_{10}(c) \right\rfloor\) such that \(b \leq c < 10b\).

Now determine the basic unit \(u\) as one of \{1, 2, 5, 10\} \(b\), depending on \(c/b \in [1, 10)\) and the two ‘bias’ coefficients, \(h = \text{high.u.bias}\) and \(f = u5.b\).
References

See Also

*axTicks* for the computation of pretty axis tick locations in plots, particularly on the log scale.

Examples

```r
pretty(1:15)          # 0  2  4  6  8 10 12 14 16
pretty(1:15, h = 2)   # 0  5 10 15
pretty(1:15, n = 4)   # 0  5 10 15
pretty(1:15 * 2)      # 0  5 10 15 20 25 30
pretty(1:20)          # 0  5 10 15 20
pretty(1:20, n = 2)   # 0 10 20
pretty(1:20, n = 10)  # 0  2  4 ... 20

for(k in 5:11) {
  cat("k=", k, ": "); print(diff(range(pretty(100 + c(0, pi*10^-k)))))
}
```

```r
##-- more bizarre, when min(x) == max(x):
pretty(pi)
```

```r
add.names <- function(v) { names(v) <- paste(v); v}
utils::str(lapply(add.names(-10:20), pretty))
utils::str(lapply(add.names(0:20), pretty, min.n = 0))
sapply( add.names(0:20), pretty, min.n = 4)
pretty(1.234e100)
pretty(1001.1001)
pretty(1001.1001, shrink = 0.2)
for(k in -7:3)
  cat("shrink=", formatC(2^k, width = 9), ": ",
       formatC(pretty(1001.1001, shrink.sml = 2^k), width = 6), 
      "\n")
```

Primitive

Description

*.Primitive* looks up by name a ‘primitive’ (internally implemented) function.

Usage

*.Primitive(name)*

Arguments

name name of the R function.
The advantage of `.Primitive` over `.Internal` functions is the potential efficiency of argument passing, and that positional matching can be used where desirable, e.g. in `switch`. For more details, see the `R Internals` manual.

All primitive functions are in the base namespace.

This function is almost never used: `name` or, more carefully, `get(name, envir = baseenv())` work equally well and do not depend on knowing which functions are primitive (which does change as R evolves).

See Also

`is.primitive` showing that primitive functions come in two types (`typeof`). `.Internal`.

**Examples**

```r
mysqrt <- .Primitive("sqrt")
c
.Internal # this one *must* be primitive!
"if" # need backticks
```

---

**Description**

`print` prints its argument and returns it `invisibly` (via `invisible(x)`). It is a generic function which means that new printing methods can be easily added for new classes.

**Usage**

```r
print(x, ...)  
```

```r
## S3 method for class 'factor'
print(x, quote = FALSE, max.levels = NULL, width = getOption("width"), ...)  
```

```r
## S3 method for class 'table'
print(x, digits = getOption("digits"), quote = FALSE, na.print = "", zero.print = "0", right = is.numeric(x) || is.complex(x), justify = "none", ...)  
```

```r
## S3 method for class 'function'
print(x, useSource = TRUE, ...)  
```

**Arguments**

- `x` an object used to select a method.
- `...` further arguments passed to or from other methods.
quote logical, indicating whether or not strings should be printed with surrounding quotes.

max.levels integer, indicating how many levels should be printed for a factor; if 0, no extra "Levels" line will be printed. The default, NULL, entails choosing max.levels such that the levels print on one line of width width.

width only used when max.levels is NULL, see above.

digits minimal number of significant digits, see print.default.

na.print character string (or NULL) indicating NA values in printed output, see print.default.

zero.print character specifying how zeros (0) should be printed; for sparse tables, using "." can produce more readable results, similar to printing sparse matrices in Matrix.

right logical, indicating whether or not strings should be right aligned.

justify character indicating if strings should left- or right-justified or left alone, passed to format.

useSource logical indicating if internally stored source should be used for printing when present, e.g., if options(keep.source = TRUE) has been in use.

Details

The default method, print.default has its own help page. Use methods("print") to get all the methods for the print generic.

print.factor allows some customization and is used for printing ordered factors as well.

print.table for printing tables allows other customization. As of R 3.0.0, it only prints a description in case of a table with 0-extents (this can happen if a classifier has no valid data).

See noquote as an example of a class whose main purpose is a specific print method.

References

See Also

The default method print.default, and help for the methods above; further options, noquote.

For more customizable (but cumbersome) printing, see cat, format or also write. For a simple prototypical print method, see .print.via.format in package tools.

Examples

require(stats)

require(stats) #-- print is the "Default function" --> print.ts(.) is called
for(i in 1:3) print(1:i)

## Printing of factors
attenu$station ## 117 levels -> 'max.levels' depending on width

## ordered factors: levels "11 < 12 < .."

esoph$agegp[1:12]
esoph$alcgp[1:12]
## Printing of sparse (contingency) tables
set.seed(521)
t1 <- round(abs(rt(200, df = 1.8)))
t2 <- round(abs(rt(200, df = 1.4)))
table(t1, t2) # simple
print(table(t1, t2), zero.print = ".") # nicer to read

## same for non-integer "table":
T <- table(t2,t1)
T <- T * (1+round(rlnorm(length(T)))/4)
print(T, zero.print = ".") # quite nicer,
print.table(T[,2:8] * 1e9, digits=3, zero.print = ".")

## still slightly inferior to Matrix::Matrix(T) for larger T

## Corner cases with empty extents:
table(1, NA) # < table of extent 1 x 0 >

---

**print.data.frame**  
**Printing Data Frames**

### Description
Print a data frame.

### Usage

```r
## S3 method for class 'data.frame'
print(x, ..., digits = NULL,
     quote = FALSE, right = TRUE, row.names = TRUE, max = NULL)
```

### Arguments

- `x`  
  object of class `data.frame`.
- `...`  
  optional arguments to print or plot methods.
- `digits`  
  the minimum number of significant digits to be used: see `print.default`.
- `quote`  
  logical, indicating whether or not entries should be printed with surrounding quotes.
- `right`  
  logical, indicating whether or not strings should be right-aligned. The default is right-alignment.
- `row.names`  
  logical (or character vector), indicating whether (or what) row names should be printed.
- `max`  
  numeric or NULL, specifying the maximal number of entries to be printed. By default, when NULL, `getOption("max.print")` used.

### Details
This calls `format` which formats the data frame column-by-column, then converts to a character matrix and dispatches to the `print` method for matrices.

When `quote = TRUE` only the entries are quoted not the row names nor the column names.
See Also
data.frame.

Examples

(dd <- data.frame(x = 1:8, f = gl(2,4), ch = I(letters[1:8])))
# print() with defaults
print(dd, quote = TRUE, row.names = FALSE)
  # suppresses row.names and quotes all entries

print.default Default Printing

Description

print.default is the default method of the generic print function which prints its argument.

Usage

## Default S3 method:
print(x, digits = NULL, quote = TRUE,
   na.print = NULL, print.gap = NULL, right = FALSE,
   max = NULL, width = NULL, useSource = TRUE, ...)

Arguments

x the object to be printed.
digits a non-null value for digits specifies the minimum number of significant digits to be printed in values. The default, NULL, uses getOption("digits"). (For the interpretation for complex numbers see signif.) Non-integer values will be rounded down, and only values greater than or equal to 1 and no greater than 22 are accepted.
quote logical, indicating whether or not strings (characters) should be printed with surrounding quotes.
a.print a character string which is used to indicate NA values in printed output, or NULL (see ‘Details’).
print.gap a non-negative integer \leq 1024, or NULL (meaning 1), giving the spacing between adjacent columns in printed vectors, matrices and arrays.
right logical, indicating whether or not strings should be right aligned. The default is left alignment.
max a non-null value for max specifies the approximate maximum number of entries to be printed. The default, NULL, uses getOption("max.print"); see that help page for more details.
width controls the maximum number of columns on a line used in printing vectors, matrices, etc. The default, NULL, uses getOption("width"); see that help page for more details including allowed values.
useSource logical, indicating whether to use source references or copies rather than deparsing language objects. The default is to use the original source if it is available.
... further arguments to be passed to or from other methods. They are ignored in this function.
Details

The default for printing NAs is to print NA (without quotes) unless this is a character NA and quote = FALSE, when ‘<NA>’ is printed.

The same number of decimal places is used throughout a vector. This means that digits specifies the minimum number of significant digits to be used, and that at least one entry will be encoded with that minimum number. However, if all the encoded elements then have trailing zeroes, the number of decimal places is reduced until at least one element has a non-zero final digit. Decimal points are only included if at least one decimal place is selected.

Attributes are printed respecting their class(es), using the values of digits to print.default, but using the default values (for the methods called) of the other arguments.

Option width controls the printing of vectors, matrices and arrays, and option deparse.cutoff controls the printing of language objects such as calls and formulae.

When the methods package is attached, print will call show for R objects with formal classes (‘S4’) if called with no optional arguments.

Large number of digits

Note that for large values of digits, currently for digits >= 16, the calculation of the number of significant digits will depend on the platform’s internal (C library) implementation of ‘sprintf()’ functionality.

Single-byte locales

If a non-printable character is encountered during output, it is represented as one of the ANSI escape sequences (‘\a’, ‘\b’, ‘\f’, ‘\n’, ‘\r’, ‘\t’, ‘\v’, ‘\ ’ and ‘\0’: see Quotes), or failing that as a 3-digit octal code: for example the UK currency pound sign in the C locale (if implemented correctly) is printed as ‘\243’. Which characters are non-printable depends on the locale. (Because some versions of Windows get this wrong, all bytes with the upper bit set are regarded as printable on Windows in a single-byte locale.)

Unicode and other multi-byte locales

In all locales, the characters in the ASCII range (‘0x00’ to ‘0x7f’) are printed in the same way, as-is if printable, otherwise via ANSI escape sequences or 3-digit octal escapes as described for single-byte locales. Whether a character is printable depends on the current locale and the operating system (C library).

Multi-byte non-printing characters are printed as an escape sequence of the form ‘\uxxxxx’ or ‘\Uxxxxxxxx’ (in hexadecimal). This is the internal code for the wide-character representation of the character. If this is not known to be Unicode code points, a warning is issued. The only known exceptions are certain Japanese ISO 2022 locales on commercial Unixes, which use a concatenation of the bytes: it is unlikely that R compiles on such a system.

It is possible to have a character string in a character vector that is not valid in the current locale. If a byte is encountered that is not part of a valid character it is printed in hex in the form ‘\xab’ and this is repeated until the start of a valid character. (This will rapidly recover from minor errors in UTF-8.)

See Also

The generic print, options. The “noquote” class and print method.
encodeString, which encodes a character vector the way it would be printed.
Examples

pi
print(pi, digits = 16)
LETTERS[1:16]
print(LETTERS, quote = FALSE)

M <- cbind(I = 1, matrix(1:10000, ncol = 10,
dimnames = list(NULL, LETTERS[1:10])))
utils::head(M)  # makes more sense than
print(M, max = 1000)  # prints 90 rows and a message about omitting 910

Description

An earlier method for printing matrices, provided for S compatibility.

Usage

prmatrix(x, rowlab =, collab =,
quote = TRUE, right = FALSE, na.print = NULL, ...)

Arguments

x numeric or character matrix.
rowlab, collab (optional) character vectors giving row or column names respectively. By def-
default, these are taken from dimnames(x).
quote logical; if TRUE and x is of mode "character", quotes (""") are used.
right if TRUE and x is of mode "character", the output columns are right-justified.
na.print how NAs are printed. If this is non-null, its value is used to represent NA.
... arguments for print methods.

Details

prmatrix is an earlier form of print.matrix, and is very similar to the S function of the same
name.

Value

Invisibly returns its argument, x.

References

Brooks/Cole.

See Also

print.default, and other print methods.
proc.time

Examples

prmatrix(m6 <- diag(6), rowlab = rep("", 6), collab = rep("", 6))

chm <- matrix(scan(system.file("help", "AnIndex", package = "splines"),
                       what = ",", , 2, byrow = TRUE)
chm # uses print.matrix()
prmatrix(chm, collab = paste("Column", 1:3), right = TRUE, quote = FALSE)

proc.time

Running Time of R

Description

proc.time determines how much real and CPU time (in seconds) the currently running \texttt{R} process has already taken.

Usage

proc.time()

Details

proc.time returns five elements for backwards compatibility, but its \texttt{print} method prints a named vector of length 3. The first two entries are the total user and system CPU times of the current \texttt{R} process and any child processes on which it has waited, and the third entry is the ‘real’ elapsed time since the process was started.

Value

An object of class "proc_time" which is a numeric vector of length 5, containing the user, system, and total elapsed times for the currently running \texttt{R} process, and the cumulative sum of user and system times of any child processes spawned by it on which it has waited. (The \texttt{print} method uses the \texttt{summary} method to combine the child times with those of the main process.)

The definition of ‘user’ and ‘system’ times is from your OS. Typically it is something like

\textit{The ‘user time’ is the CPU time charged for the execution of user instructions of the calling process. The ‘system time’ is the CPU time charged for execution by the system on behalf of the calling process.}

Times of child processes are not available on Windows and will always be given as \texttt{NA}.

The resolution of the times will be system-specific and on Unix-alikes times are rounded down to milliseconds. On modern systems they will be that accurate, but on older systems they might be accurate to 1/100 or 1/60 sec. They are typically available to 10ms on Windows.

This is a \texttt{primitive} function.

References

prod

See Also

system.time for timing an R expression, gc.time for how much of the time was spent in garbage collection.

setTimeLimit to limit the CPU or elapsed time for the session or an expression.

Examples

```r
## a way to time an R expression: system.time is preferred
ptm <- proc.time()
for (i in 1:50) mad(stats::runif(500))
proc.time() - ptm
```

prod

Product of Vector Elements

Description

prod returns the product of all the values present in its arguments.

Usage

```r
prod(..., na.rm = FALSE)
```

Arguments

- `...` numeric or complex or logical vectors.
- `na.rm` logical. Should missing values be removed?

Details

If `na.rm` is FALSE an NA value in any of the arguments will cause a value of NA to be returned, otherwise NA values are ignored.

This is a generic function: methods can be defined for it directly or via the Summary group generic. For this to work properly, the arguments `...` should be unnamed, and dispatch is on the first argument.

Logical true values are regarded as one, false values as zero. For historical reasons, NULL is accepted and treated as if it were numeric(0).

Value

The product, a numeric (of type "double") or complex vector of length one. NB: the product of an empty set is one, by definition.

S4 methods

This is part of the S4 Summary group generic. Methods for it must use the signature `x, ..., na.rm`.

Express Table Entries as Fraction of Marginal Table

Description

Returns conditional proportions given margins, i.e. entries of x, divided by the appropriate marginal sums.

Usage

proportions(x, margin = NULL)
prop.table(x, margin = NULL)

Arguments

x  
table

margin  
a vector giving the margins to split by. E.g., for a matrix 1 indicates rows, 2 indicates columns, c(1,2) indicates rows and columns. When x has named dimnames, it can be a character vector selecting dimension names.

Value

Table like x expressed relative to margin

Note

prop.table is an earlier name, retained for back-compatibility.

Author(s)

Peter Dalgaard

See Also

marginSums, apply, sweep are a more general mechanism for sweeping out marginal statistics.
Examples

```r
m <- matrix(1:4, 2)
m
proportions(m, 1)

DF <- as.data.frame(UCBAdmissions)
tbl <- xtabs(Freq ~ Gender + Admit, DF)
proportions(tbl, "Gender")
```

**pushBack**

*Push Text Back on to a Connection*

**Description**

Functions to push back text lines onto a connection, and to enquire how many lines are currently pushed back.

**Usage**

```r
pushBack(data, connection, newLine = TRUE, encoding = c("", "bytes", "UTF-8"))
pushBackLength(connection)
clearPushBack(connection)
```

**Arguments**

- `data` : a character vector.
- `connection` : A connection.
- `newLine` : logical. If true, a newline is appended to each string pushed back.
- `encoding` : character string, partially matched. See details.

**Details**

Several character strings can be pushed back on one or more occasions. The occasions form a stack, so the first line to be retrieved will be the first string from the last call to `pushBack`. Lines which are pushed back are read prior to the normal input from the connection, by the normal text-reading functions such as `readLines` and `scan`.

Pushback is only allowed for readable connections in text mode.

Not all uses of connections respect pushbacks, in particular the input connection is still wired directly, so for example parsing commands from the console and `scan("")` ignore pushbacks on `stdin`.

When character strings with a marked encoding (see `Encoding`) are pushed back they are converted to the current encoding if `encoding = ""`. This may involve representing characters as `<U+xxxx>` if they cannot be converted. They will be converted to UTF-8 if `encoding = "UTF-8"` or left as-is if `encoding = "bytes"`.

**Value**

`pushBack` and `clearPushBack()` return nothing, invisibly.
`pushBackLength` returns the number of lines currently pushed back.
See Also
colors, readLines.

Examples
zz <- textConnection(LETTERS)
readLines(zz, 2)
pushBack(c("aa", "bb"), zz)
pushBackLength(zz)
readLines(zz, 1)
pushBackLength(zz)
readLines(zz, 1)
readLines(zz, 1)
close(zz)

qr
The QR Decomposition of a Matrix

Description

qr computes the QR decomposition of a matrix.

Usage

qr(x, ...)
## Default S3 method:
qr(x, tol = 1e-07 , LAPACK = FALSE, ...)

qr.coef(qr, y)
qr.qy(qr, y)
qr.qty(qr, y)
qr.resid(qr, y)
qr.fitted(qr, y, k = qr$rank)
qr.solve(a, b, tol = 1e-7)
## S3 method for class 'qr'
solve(a, b, ...)

is.qr(x)
as.qr(x)

Arguments

x a numeric or complex matrix whose QR decomposition is to be computed. Logical matrices are coerced to numeric.
tol the tolerance for detecting linear dependencies in the columns of x. Only used if LAPACK is false and x is real.
qr a QR decomposition of the type computed by qr.
y, b a vector or matrix of right-hand sides of equations.
a a QR decomposition or (qr.solve only) a rectangular matrix.
k effective rank.
LAPACK logical. For real x, if true use LAPACK otherwise use LINPACK (the default).
... further arguments passed to or from other methods
Details

The QR decomposition plays an important role in many statistical techniques. In particular it can be used to solve the equation $Ax = b$ for given matrix $A$, and vector $b$. It is useful for computing regression coefficients and in applying the Newton-Raphson algorithm.

The functions `qr.coef`, `qr.resid`, and `qr.fitted` return the coefficients, residuals and fitted values obtained when fitting $y$ to the matrix with QR decomposition `qr`. (If pivoting is used, some of the coefficients will be NA.) `qr.qy` and `qr.qty` return $Q \%\% y$ and $t(Q) \%\% y$, where $Q$ is the (complete) $Q$ matrix.

All the above functions keep dimnames (and names) of $x$ and $y$ if there are any.

`solve.qr` is the method for `solve` for QR objects. `qr.solve` solves systems of equations via the QR decomposition: if $a$ is a QR decomposition it is the same as `solve.qr`, but if $a$ is a rectangular matrix the QR decomposition is computed first. Either will handle over- and under-determined systems, providing a least-squares fit if appropriate.

`is.qr` returns TRUE if $x$ is a list and inherits from "qr".

It is not possible to coerce objects to mode "qr". Objects either are QR decompositions or they are not.

The LINPACK interface is restricted to matrices $x$ with less than $2^{31}$ elements.

`qr.fitted` and `qr.resid` only support the LINPACK interface.

Unsuccessful results from the underlying LAPACK code will result in an error giving a positive error code: these can only be interpreted by detailed study of the FORTRAN code.

Value

The QR decomposition of the matrix as computed by LINPACK(*) or LAPACK. The components in the returned value correspond directly to the values returned by DQRDC(2)/DGEQP3/ZGEQP3.

- `qr` a matrix with the same dimensions as $x$. The upper triangle contains the $R$ of the decomposition and the lower triangle contains information on the $Q$ of the decomposition (stored in compact form). Note that the storage used by DQRDC and DGEQP3 differs.
- `qraux` a vector of length `ncol(x)` which contains additional information on $Q$.
- `rank` the rank of $x$ as computed by the decomposition(*): always full rank in the LAPACK case.
- `pivot` information on the pivoting strategy used during the decomposition.

Non-complex QR objects computed by LAPACK have the attribute "useLAPACK" with value TRUE.

*) `dqrdc2` instead of LINPACK’s DQRDC

In the (default) LINPACK case (LAPACK = FALSE), `qr()` uses a modified version of LINPACK’s DQRDC, called ‘dqrdc2’. It differs by using the tolerance tol for a pivoting strategy which moves columns with near-zero 2-norm to the right-hand edge of the $x$ matrix. This strategy means that sequential one degree-of-freedom effects can be computed in a natural way.

Note

To compute the determinant of a matrix (do you really need it?), the QR decomposition is much more efficient than using Eigen values (`eigen`). See `det`.

Using LAPACK (including in the complex case) uses column pivoting and does not attempt to detect rank-deficient matrices.
For `qr`, the LINPACK routine `DQRDC` (but modified to `dqrdc2(*)`) and the LAPACK routines `DGEQP3` and `ZGEQP3`. Further LINPACK and LAPACK routines are used for `qr.coef`, `qr.qy` and `qr.aty`.

LAPACK and LINPACK are from [https://www.netlib.org/lapack/](https://www.netlib.org/lapack/) and [https://www.netlib.org/linpack/](https://www.netlib.org/linpack/) and their guides are listed in the references.

### See Also

`det` (using `qr`) to compute the determinant of a matrix.

### Examples

```r
hilbert <- function(n) { i <- 1:n; 1 / outer(i - 1, i, "+") }
h9 <- hilbert(9); h9
qr(h9)$rank; h9
##--> only 7
qrh9 <- qr(h9, tol = 1e-10)
qrh9$rank
##--> 9
###-- Solve linear equation system H %*% x = y :
y <- 1:9/10
x <- qr.solve(h9, y, tol = 1e-10)  # or equivalently :
x <- qr.coef(qrh9, y)  #-- is == but much better than
                         #-- solve(h9) %*% y
h9 %*% x  # y

## overdetermined system
A <- matrix(runif(12), 4)
b <- 1:4
qr.solve(A, b)  # or solve(qr(A), b)
solve(qr(A, LAPACK = TRUE), b)
# this is a least-squares solution, cf. lm(b ~ 0 + A)

## underdetermined system
A <- matrix(runif(12), 3)
b <- 1:3
qr.solve(A, b)
solve(qr(A, LAPACK = TRUE), b)
# solutions will have one zero, not necessarily the same one
```
QR.Auxiliaries

Reconstruct the Q, R, or X Matrices from a QR Object

Description

Returns the original matrix from which the object was constructed or the components of the decomposition.

Usage

qr.X(qr, complete = FALSE, ncol =)
qr.Q(qr, complete = FALSE, Dvec =)
qr.R(qr, complete = FALSE)

Arguments

qr object representing a QR decomposition. This will typically have come from a previous call to qr or lsfit.

complete logical expression of length 1. Indicates whether an arbitrary orthogonal completion of the Q or X matrices is to be made, or whether the R matrix is to be completed by binding zero-value rows beneath the square upper triangle.

ncol integer in the range 1:nrow(qr$qr$). The number of columns to be in the reconstructed X. The default when complete is FALSE is the first min(ncol(X),nrow(X)) columns of the original X from which the qr object was constructed. The default when complete is TRUE is a square matrix with the original X in the first ncol(X) columns and an arbitrary orthogonal completion (unitary completion in the complex case) in the remaining columns.

Dvec vector (not matrix) of diagonal values. Each column of the returned Q will be multiplied by the corresponding diagonal value. Defaults to all 1s.

Value

qr.X returns X, the original matrix from which the qr object was constructed, provided ncol(X) <= nrow(X). If complete is TRUE or the argument ncol is greater than ncol(X), additional columns from an arbitrary orthogonal (unitary) completion of X are returned.

qr.Q returns part or all of Q, the order-nrow(X) orthogonal (unitary) transformation represented by qr. If complete is TRUE, Q has nrow(X) columns. If complete is FALSE, Q has ncol(X) columns. When Dvec is specified, each column of Q is multiplied by the corresponding value in Dvec.

Note that qr.Q(qr,*) is a special case of qr.qy(qr,y) (with a “diagonal” y), and qr.X(qr,*) is basically qr.qy(qr,R) (apart from pivoting and dimnames setting).

qr.R returns R. This may be pivoted, e.g., if a <- qr(x) then x[, a$pivot] = QR. The number of rows of R is either nrow(X) or ncol(X) (and may depend on whether complete is TRUE or FALSE).

See Also

qr, qr.qy.
**Examples**

```r
p <- ncol(x <- LifeCycleSavings[, -1]) # not the 'sr'
qrstr <- qr(x) # dim(x) == c(n,p)
qrstr $ rank # == 4 == p
Q <- qr.Q(qrstr) # dim(Q) == dim(x)
R <- qr.R(qrstr) # dim(R) == ncol(x)
X <- qr.X(qrstr) # X == x
range(X - as.matrix(x)) # ~ < 6e-12
## X == Q %*% R if there has been no pivoting, as here:
all.equal(unname(X),
  unname(Q %*% R))

# example of pivoting
x <- cbind(int = 1,
  b1 = rep(1:0, each = 3), b2 = rep(0:1, each = 3),
  c1 = rep(c(1,0,0), 2), c2 = rep(c(0,1,0), 2), c3 = rep(c(0,0,1),2))
X # is singular, columns "b2" and "c3" are "extra"
a <- qr(x)
zapsmall(qr.R(a)) # columns are int b1 c1 c2 b2 c3
a$pivot
pivI <- sort.list(a$pivot) # the inverse permutation
all.equal(x, qr.Q(a) %*% qr.R(a)) # no, no
stopifnot(  
  all.equal(x[, a$pivot], qr.Q(a) %*% qr.R(a)),
  all.equal(x , qr.Q(a) %*% qr.R(a)[, pivI])) # TRUE too!
```

**Description**

The function `quit` or its alias `q` terminate the current R session.

**Usage**

```r
quit(save = "default", status = 0, runLast = TRUE)
q(save = "default", status = 0, runLast = TRUE)
```

**Arguments**

- `save` a character string indicating whether the environment (workspace) should be saved, one of "no", "yes", "ask" or "default".
- `status` the (numerical) error status to be returned to the operating system, where relevant. Conventionally 0 indicates successful completion.
- `runLast` should `.Last()` be executed?

**Details**

`save` must be one of "no", "yes", "ask" or "default". In the first case the workspace is not saved, in the second it is saved and in the third the user is prompted and can also decide not to quit. The default is to ask in interactive use but may be overridden by command-line arguments (which must be supplied in non-interactive use).
Immediately *before* normal termination, `.Last()` is executed if the function `.Last` exists and `runLast` is true. If in interactive use there are errors in the `.Last` function, control will be returned to the command prompt, so do test the function thoroughly. There is a system analogue, `.Last.sys()`, which is run after `.Last()` if `runLast` is true.

Exactly what happens at termination of an *R* session depends on the platform and GUI interface in use. A typical sequence is to run `.Last()` and `.Last.sys()` (unless `runLast` is false), to save the workspace if requested (and in most cases also to save the session history: see `savehistory`), then run any finalizers (see `reg.finalizer`) that have been set to be run on exit, close all open graphics devices, remove the session temporary directory and print any remaining warnings (e.g., from `.Last()` and device closure).

Some error status values are used by *R* itself. The default error handler for non-interactive use effectively calls `q("no",1,TRUE)` and returns error status 1. Error status 2 is used for *R* 'suicide', that is a catastrophic failure, and other small numbers are used by specific ports for initialization failures. It is recommended that users choose statuses of 10 or more.

Valid values of `status` are system-dependent, but 0:255 are normally valid. (Many OSes will report the last byte of the value, that is report the value modulo 256. But not all.)

**Warning**

The value of `.Last` is for the end user to control: as it can be replaced later in the session, it cannot safely be used programmatically, e.g. by a package. The other way to set code to be run at the end of the session is to use a *finalizer*: see `reg.finalizer`.

**Note**

The *R*.app GUI on macOS has its own version of these functions with slightly different behaviour for the `save` argument (the GUI’s ‘Startup’ preferences for this action are taken into account).

**References**

**See Also**

`.First` for setting things on startup.

**Examples**

```r
## Not run: ## Unix-flavour example
.Last <- function() {
  graphics.off() # close devices before printing
  cat("Now sending PDF graphics to the printer:\n")
  system("lpr Rplots.pdf")
  cat("bye bye...\n")
}
quit("yes")
## End(Not run)
```
Description

Descriptions of the various uses of quoting in R.

Details

Three types of quotes are part of the syntax of R: single and double quotation marks and the backtick (or back quote, ‘’’). In addition, backslash is used to escape the following character inside character constants.

Character constants

Single and double quotes delimit character constants. They can be used interchangeably but double quotes are preferred (and character constants are printed using double quotes), so single quotes are normally only used to delimit character constants containing double quotes.

Backslash is used to start an escape sequence inside character constants. Escaping a character not in the following table is an error.

Single quotes need to be escaped by backslash in single-quoted strings, and double quotes in double-quoted strings.

'\n' newline
'\r' carriage return
'\t' tab
'\b' backspace
'\a' alert (bell)
'\f' form feed
'\v' vertical tab
'\' backslash ‘’
'\'' ASCII apostrophe ‘’’
'\''' ASCII quotation mark ‘”’
'\'' ASCII grave accent (backtick) ‘’’
'\nnnn' character with given octal code (1, 2 or 3 digits)
'\xnnn' character with given hex code (1 or 2 hex digits)
'\unnnnnn' Unicode character with given code (1–4 hex digits)
'\Uunnnnnnnn' Unicode character with given code (1–8 hex digits)

Alternative forms for the last two are ‘\u{nnnn}’ and ‘\U{nnnnnnnn}’. All except the Unicode escape sequences are also supported when reading character strings by scan and read.table if allowEscapes = TRUE. Unicode escapes can be used to enter Unicode characters not in the current locale’s charset (when the string will be stored internally in UTF-8).

The parser does not allow the use of both octal/hex and Unicode escapes in a single string.

These forms will also be used by print.default when outputting non-printable characters (including backslash).

Embedded nuls are not allowed in character strings, so using escapes (such as ‘\0’) for a nul will result in the string being truncated at that point (usually with a warning).
Raw character constants are also available using a syntax similar to the one used in C++: \texttt{\textquotesingle\textquotesingle}(\ldots)\text{\textquoteright\textquoteright} with \ldots any character sequence, except that it must not contain the closing sequence \texttt{\textquotesingle\textquotesingle}(\textquotesingle). The delimiter pairs \texttt{\textbackslash{}-} and \texttt{\{}\texttt{\textbackslash{}-} can also be used, and \texttt{R} can be used in place of \texttt{r}. For additional flexibility, a number of dashes can be placed between the opening quote and the opening delimiter, as long as the same number of dashes appear between the closing delimiter and the closing quote.

Names and Identifiers

Identifiers consist of a sequence of letters, digits, the period (\texttt{.}) and the underscore. They must not start with a digit nor underscore, nor with a period followed by a digit. \texttt{Reserved} words are not valid identifiers.

The definition of a \textit{letter} depends on the current locale, but only ASCII digits are considered to be digits.

Such identifiers are also known as syntactic names and may be used directly in \texttt{R} code. Almost always, other names can be used provided they are quoted. The preferred quote is the backtick (\texttt{\textbackslash{}}), and \texttt{deparse} will normally use it, but under many circumstances single or double quotes can be used (as a character constant will often be converted to a name). One place where backticks may be essential is to delimit variable names in formulae: see \texttt{formula}.

See Also

\texttt{Syntax} for other aspects of the syntax.
\texttt{sQuote} for quoting English text.
\texttt{shQuote} for quoting OS commands.

The \texttt{R Language Definition} manual.

Examples

\begin{verbatim}
'single quotes can be used more-or-less interchangeably'
"with double quotes to create character vectors"

### Single quotes inside single-quoted strings need backslash-escaping.
### Ditto double quotes inside double-quoted strings.
### identical("It\'s alive!", he screamed.
   "It\'s alive!", he screamed.") # same

### Backslashes need doubling, or they have a special meaning.
x <- "In ALGOL, you could do logical AND with /\\."
print(x) # shows it as above ("input-like")
writeLines(x) # shows it as you like it ;-)  

### Single backslashes followed by a letter are used to denote
### special characters like tab(ulator)s and newlines:
x <- "long\tlines can be\nbroken with newlines"
writeLines(x) # see also \texttt{?strwrap}

### Backticks are used for non-standard variable names.
### (See \texttt{make.names} and \texttt{?Reserved} for what counts as
### non-standard.)
x y <- 1:5
x y
d <- data.frame(\'1st column\' =rchisq(5, 2), check.names = FALSE)
d$\'1st column\'
\end{verbatim}
Backslashes followed by up to three numbers are interpreted as octal notation for ASCII characters. 
"\110\145\154\154\157\40\127\157\162\154\144\41"

\x followed by up to two numbers is interpreted as hexadecimal notation for ASCII characters. 
(hw1 <- "\x48\x65\x6c\x6c\x6f\x20\x57\x6f\x72\x6c\x64\x21")

Mixing octal and hexadecimal in the same string is OK 
(hw2 <- "\110\x65\x6c\x6c\x6f\x20\x57\x6f\x72\x6c\x64\x21")

\u is also hexadecimal, but supported up to 4 numbers, using Unicode specification. In the previous example, you can simply replace \x with \u. 
(hw3 <- "\u48\u65\u6c\u6c\u6f\u20\u57\u6f\u72\u6c\u64\u21")

The last three are all identical to hw <- "Hello World!"
stopifnot(identical(hw, hw1), identical(hw1, hw2), identical(hw2, hw3))

Using Unicode makes more sense for non-latin characters. 
(nn <- "\u0126\u0119\u1114\u022d\u2001\u03e2\u0954\u0f3f\u13d3\u147b\u203c")

Mixing \x and \u throws a _parse_ error (which is not catchable!) 
Not run: "\x48\u65\x6c\x6f\x20\x57\x6f\x72\x6c\x64\x21"

End(Not run)
# Error: mixing Unicode and octal/hex escapes ....

\U works like \u, but supports up to eight numbers. 
So we can replace \u with \U in the previous example. 
n2 <- "\U0126\U0119\U1114\U022d\U0201\U03e2\U0954\U0f3f\U13d3\U147b\U203c"
stopifnot(identical(nn, n2))

Under systems supporting multi-byte locales (and not Windows), \U also supports the rarer characters outside the usual 16^4 range. 
See the R language manual, 
https://cran.r-project.org/doc/manuals/r-release/R-lang.html#Literal-constants

# and bug 16098 https://bugs.r-project.org/bugzilla3/show_bug.cgi?id=16098
"\U1d4d7" # On Windows this gives the incorrect value of "\Ud4d7"

nul characters (for terminating strings in C) are not allowed (parse errors) 
Not run: 
"foo\0bar" # Error: nul character not allowed (line 1)
"foo\u0000bar" # same error

End(Not run)

A Windows path written as a raw string constant: 
r"(c:\Program files\R)"

More raw strings: 
r"{(1\12)}"
r"(use both "double' and 'single' quotes)"
r"---(\1---)----"
**R.Version**

### Description

`R.Version()` provides detailed information about the version of R running.

`R.version` is a variable (a `list`) holding this information (and `version` is a copy of it for S compatibility).

### Usage

- `R.Version()
- R.version
- R.version.string
- version`

### Details

This gives details of the OS under which R was built, not the one under which it is currently running (for which see `Sys.info`).

Note that OS names might not be what you expect: for example macOS Mavericks 10.9.4 identifies itself as `darwin13.3.0`, Linux usually as `linux-gnu` and Solaris 10 as `solaris2.10`.

### Value

`R.Version` returns a list with character-string components

- **platform**
  - the platform for which R was built. A triplet of the form CPU-VENDOR-OS, as determined by the configure script. E.g., "i686-unknown-linux-gnu" or "i386-pc-mingw32".

- **arch**
  - the architecture (CPU) R was built on/for.

- **os**
  - the underlying operating system.

- **system**
  - CPU and OS, separated by a comma.

- **status**
  - the status of the version (e.g., "alpha")

- **major**
  - the major version number

- **minor**
  - the minor version number, including the patchlevel

- **year**
  - the year the version was released

- **month**
  - the month the version was released

- **day**
  - the day the version was released

- **svn rev**
  - the Subversion revision number, which should be either “unknown” or a single number. (A range of numbers or a number with ‘M’ or ‘S’ appended indicates inconsistencies in the sources used to build this version of R.)

- **language**
  - always “R”.

- **version.string**
  - a character string concatenating some of the info above, useful for plotting, etc.

`R.version` and `version` are lists of class "simple.list" which has a print method.
Note

Do *not* use `R.version$os` to test the platform the code is running on: use `.Platform$OS.type` instead. Slightly different versions of the OS may report different values of `R.version$os`, as may different versions of `R`. `R.version.string` is a copy of `R.version$version.string` for simplicity and backwards compatibility.

See Also

`sessionInfo` which provides additional information; `getRversion` typically used inside `R` code, `.Platform`, `Sys.info`.

Examples

```r
require(graphics)

R.version$os # to check how lucky you are ...
plot(0) # any plot
mtext(R.version.string, side = 1, line = 4, adj = 1) # a useful bottom-right note

## a good way to detect macOS:
if(grepl("^darwin", R.version$os)) message("running on macOS")

## Short R version string, ("space free", useful in file/directory names;
## also fine for unreleased versions of R):
shortRversion <- function() {
  rvs <- R.version.string
  if(grepl("devel", (st <- R.version$status)))
    rvs <- sub(paste0(" ",st," "), "-devel_", rvs, fixed=TRUE)
  gsub("[()]", ",", gsub(" ", ",", sub(" version ", "-", rvs)))
}
shortRversion()
```

Random Number Generation

Description

`.Random.seed` is an integer vector, containing the random number generator (RNG) state for random number generation in `R`. It can be saved and restored, but should not be altered by the user.

`RNGkind` is a more friendly interface to query or set the kind of RNG in use.

`RNGversion` can be used to set the random generators as they were in an earlier `R` version (for reproducibility).

`set.seed` is the recommended way to specify seeds.

Usage

```r
(Random.seed <- c(rng.kind, n1, n2, ...))
RNGkind(kind = NULL, normal.kind = NULL, sample.kind = NULL)
RNGversion(vstr)
set.seed(seed, kind = NULL, normal.kind = NULL, sample.kind = NULL)
```
Arguments

kind character or NULL. If kind is a character string, set R’s RNG to the kind desired. Use "default" to return to the R default. See ‘Details’ for the interpretation of NULL.

normal.kind character string or NULL. If it is a character string, set the method of Normal generation. Use "default" to return to the R default. NULL makes no change.

sample.kind character string or NULL. If it is a character string, set the method of discrete uniform generation (used in sample, for instance). Use "default" to return to the R default. NULL makes no change.

seed a single value, interpreted as an integer, or NULL (see ‘Details’).

vstr a character string containing a version number, e.g., "1.6.2". The default RNG configuration of the current R version is used if vstr is greater than the current version.

rng.kind integer code in 0:k for the above kind.

n1, n2, ... integers. See the details for how many are required (which depends on rng.kind).

Details

The currently available RNG kinds are given below. kind is partially matched to this list. The default is "Mersenne-Twister".

"Wichmann-Hill" The seed, .Random.seed[-1] == r[1:3] is an integer vector of length 3, where each r[1] is in 1:(p[i]-1), where p is the length 3 vector of primes, p = (30269, 30307, 30323). The Wichmann–Hill generator has a cycle length of $6.9536 \times 10^{12}$ (= prod(p-1)/4, see Applied Statistics (1984) 33, 123 which corrects the original article).

"Marsaglia-Multicarry": A multiply-with-carry RNG is used, as recommended by George Marsaglia in his post to the mailing list ‘sci.stat.math’. It has a period of more than $2^{60}$ and has passed all tests (according to Marsaglia). The seed is two integers (all values allowed).

"Super-Duper": Marsaglia’s famous Super-Duper from the 70’s. This is the original version which does not pass the MTUPLE test of the Diehard battery. It has a period of approximately $4.6 \times 10^{18}$ for most initial seeds. The seed is two integers (all values allowed for the first seed: the second must be odd).

We use the implementation by Reeds et al (1982–84).

The two seeds are the Tausworthe and congruence long integers, respectively. A one-to-one mapping to S’s .Random.seed[1:12] is possible but we will not publish one, not least as this generator is not exactly the same as that in recent versions of S-PLUS.

"Mersenne-Twister": From Matsumoto and Nishimura (1998); code updated in 2002. A twisted GFSR with period $2^{19937} - 1$ and equidistribution in 623 consecutive dimensions (over the whole period). The ‘seed’ is a 624-dimensional set of 32-bit integers plus a current position in that set.

R uses its own initialization method due to B. D. Ripley and is not affected by the initialization issue in the 1998 code of Matsumoto and Nishimura addressed in a 2002 update.

"Knuth-TAOCP-2002": A 32-bit integer GFSR using lagged Fibonacci sequences with subtraction. That is, the recurrence used is

$$X_j = (X_{j-100} - X_{j-37}) \mod 2^{30}$$

and the ‘seed’ is the set of the 100 last numbers (actually recorded as 101 numbers, the last being a cyclic shift of the buffer). The period is around $2^{129}$. 

The 2002 version was not backwards compatible with the earlier version: the initialization of the GFSR from the seed was altered. R did not allow you to choose consecutive seeds, the reported ‘weakness’, and already scrambled the seeds.

Initialization of this generator is done in interpreted R code and so takes a short but noticeable time.

"L’Ecuyer–CMRG": A ‘combined multiple-recursive generator’ from L’Ecuyer (1999), each element of which is a feedback multiplicative generator with three integer elements: thus the seed is a (signed) integer vector of length 6. The period is around $2^{191}$.

The 6 elements of the seed are internally regarded as 32-bit unsigned integers. Neither the first three nor the last three should be all zero, and they are limited to less than 4294967087 and 4294944443 respectively.

This is not particularly interesting of itself, but provides the basis for the multiple streams used in package parallel.

"user-supplied": Use a user-supplied generator. See Random.user for details.

normal.kind can be "Kinderman-Ramage", "Buggy Kinderman-Ramage" (not for set.seed), "Ahrens-Dieter", "Box-Muller", "Inversion" (the default), or "user-supplied". (For inversion, see the reference in qnorm.) The Kinderman-Ramage generator used in versions prior to 1.7.0 (now called "Buggy") had several approximation errors and should only be used for reproduction of old results. The "Box-Muller" generator is stateful as pairs of normals are generated and returned sequentially. The state is reset whenever it is selected (even if it is the current normal generator) and when kind is changed.

sample.kind can be "Rounding" or "Rejection", or partial matches to these. The former was the default in versions prior to 3.6.0: it made sample noticeably non-uniform on large populations, and should only be used for reproduction of old results. See PR#17494 for a discussion.

set.seed uses a single integer argument to set as many seeds as are required. It is intended as a simple way to get quite different seeds by specifying small integer arguments, and also as a way to get valid seed sets for the more complicated methods (especially "Mersenne-Twister" and "Knuth–TAOCP"). There is no guarantee that different values of seed will seed the RNG differently, although any exceptions would be extremely rare. If called with seed = NULL it re-initializes (see ‘Note’) as if no seed had yet been set.

The use of kind = NULL, normal.kind = NULL or sample.kind = NULL in RNGkind or set.seed selects the currently-used generator (including that used in the previous session if the workspace has been restored); if no generator has been used it selects "default".

Value

Random.seed is an integer vector whose first element codes the kind of RNG and normal generator. The lowest two decimal digits are in 0:(k-1) where k is the number of available RNGs. The hundreds represent the type of normal generator (starting at 0), and the ten thousands represent the type of discrete uniform sampler.

In the underlying C, .Random.seed[-1] is unsigned; therefore in R .Random.seed[-1] can be negative, due to the representation of an unsigned integer by a signed integer.

RNGkind returns a three-element character vector of the RNG, normal and sample kinds selected before the call, invisibly if either argument is not NULL. A type starts a session as the default, and is selected either by a call to RNGkind or by setting .Random.seed in the workspace. (NB: prior to R 3.6.0 the first two kinds were returned in a two-element character vector.)

RNGversion returns the same information as RNGkind about the defaults in a specific R version.

set.seed returns NULL, invisibly.
Note

Initially, there is no seed; a new one is created from the current time and the process ID when one is required. Hence different sessions will give different simulation results, by default. However, the seed might be restored from a previous session if a previously saved workspace is restored.

`.Random.seed` saves the seed set for the uniform random-number generator, at least for the system generators. It does not necessarily save the state of other generators, and in particular does not save the state of the Box–Muller normal generator. If you want to reproduce work later, call `set.seed` (preferably with explicit values for `kind` and `normal.kind`) rather than set `.Random.seed`.

The object `.Random.seed` is only looked for in the user’s workspace.

Do not rely on randomness of low-order bits from RNGs. Most of the supplied uniform generators return 32-bit integer values that are converted to doubles, so they take at most $2^{32}$ distinct values and long runs will return duplicated values (Wichmann-Hill is the exception, and all give at least 30 varying bits.)

## ----
Random.user

Description

Function RNGkind allows user-coded uniform and normal random number generators to be supplied. The details are given here.

Details

A user-specified uniform RNG is called from entry points in dynamically-loaded compiled code. The user must supply the entry point user_unif_rand, which takes no arguments and returns a pointer to a double. The example below will show the general pattern. The generator should have at least 25 bits of precision.

Optionally, the user can supply the entry point user_unif_init, which is called with an unsigned int argument when RNGkind (or set.seed) is called, and is intended to be used to initialize the user’s RNG code. The argument is intended to be used to set the ‘seeds’; it is the seed argument to set.seed or an essentially random seed if RNGkind is called.

If only these functions are supplied, no information about the generator’s state is recorded in .Random.seed. Optionally, functions user_unif_nseed and user_unif_seedloc can be supplied which are called with no arguments and should return pointers to the number of seeds and to an integer (specifically, ‘Int32’) array of seeds. Calls to GetRNGstate and PutRNGstate will then copy this array to and from .Random.seed.

A user-specified normal RNG is specified by a single entry point user_norm_rand, which takes no arguments and returns a pointer to a double.

Warning

As with all compiled code, mis-specifying these functions can crash R. Do include the ‘R_ext/Random.h’ header file for type checking.

Examples

## Not run:
## Marsaglia's congruential PRNG
#include <R_ext/Random.h>

static Int32 seed;
static double res;
static int nseed = 1;

double * user_unif_rand()
{
    seed = 69069 * seed + 1;
    res = seed * 2.32830643653869e-10;
    return &res;
}
range

 returns a vector containing the minimum and maximum of all the given arguments.

Usage

range(..., na.rm = FALSE)

## Default S3 method:
range(..., na.rm = FALSE, finite = FALSE)

Arguments

... any numeric or character objects.
na.rm logical, indicating if NA’s should be omitted.
finite logical, indicating if all non-finite elements should be omitted.
Details

range is a generic function: methods can be defined for it directly or via the `Summary` group generic. For this to work properly, the arguments ... should be unnamed, and dispatch is on the first argument.

If `na.rm` is FALSE, NA and NaN values in any of the arguments will cause NA values to be returned, otherwise NA values are ignored.

If `finite` is TRUE, the minimum and maximum of all finite values is computed, i.e., `finite = TRUE` includes `na.rm = TRUE`.

A special situation occurs when there is no (after omission of NAs) nonempty argument left, see `min`.

S4 methods

This is part of the S4 `Summary` group generic. Methods for it must use the signature `x, ..., na.rm`.

References

`min`, `max`.

The `extendrange()` utility in package `grDevices`.

Examples

```r
(r.x <- range(stats::rnorm(100)))
diff(r.x) # the SAMPLE range

x <- c(NA, 1:3, -1:1/0); x
range(x)
range(x, na.rm = TRUE)
range(x, finite = TRUE)
```

---

**rank**

### Sample Ranks

**Description**

Returns the sample ranks of the values in a vector. Ties (i.e., equal values) and missing values can be handled in several ways.

**Usage**

```r
rank(x, na.last = TRUE,
     ties.method = c("average", "first", "last", "random", "max", "min"))
```
**Arguments**

- **x**: a numeric, complex, character or logical vector.
- **na.last**: for controlling the treatment of NAs. If TRUE, missing values in the data are put last; if FALSE, they are put first; if NA, they are removed; if "keep" they are kept with rank NA.
- **ties.method**: a character string specifying how ties are treated, see ‘Details’; can be abbreviated.

**Details**

If all components are different (and no NAs), the ranks are well defined, with values in `seq_along(x)`. With some values equal (called ‘ties’), the argument ties.method determines the result at the corresponding indices. The "first" method results in a permutation with increasing values at each index set of ties, and analogously "last" with decreasing values. The "random" method puts these in random order whereas the default, "average", replaces them by their mean, and "max" and "min" replaces them by their maximum and minimum respectively, the latter being the typical sports ranking.

NA values are never considered to be equal: for na.last = TRUE and na.last = FALSE they are given distinct ranks in the order in which they occur in x.

**NB**: rank is not itself generic but `xtfrm` is, and `rank(xtfrm(x),....)` will have the desired result if there is a `xtfrm` method. Otherwise, `rank` will make use of `==`, `>`, `is.na` and extraction methods for classed objects, possibly rather slowly.

**Value**

A numeric vector of the same length as x with names copied from x (unless na.last = NA, when missing values are removed). The vector is of integer type unless x is a long vector or ties.method = "average" when it is of double type (whether or not there are any ties).

**References**

**See Also**

`order` and `sort`; `xtfrm`, see above.

**Examples**

```r
(r1 <- rank(x1 <- c(3, 1, 4, 15, 92)))
x2 <- c(3, 1, 4, 1, 5, 9, 2, 6, 5, 3, 5)
names(x2) <- letters[1:11]
(r2 <- rank(x2)) # ties are averaged

## rank() is "idempotent": rank(rank(x)) == rank(x):
stopifnot(rank(r1) == r1, rank(r2) == r2)

## ranks without averaging
rank(x2, ties.method= "first") # first occurrence wins
rank(x2, ties.method= "last" ) # last occurrence wins
rank(x2, ties.method= "random") # ties broken at random
rank(x2, ties.method= "random") # and again
```
### keep ties ties, no average

\(\text{rma} \leftarrow \text{rank}(x2, \text{ties.method} = \text{"max"})\)  # as used classically
\(\text{rmi} \leftarrow \text{rank}(x2, \text{ties.method} = \text{"min"})\)  # as in Sports
\(\text{stopifnot}(\text{rma} + \text{rmi} == \text{round}(r2 + r2))\)

### Comparing all tie.methods:

\(\text{tMeth} \leftarrow \text{eval(formals(rank)$ties.method)}\)
\(\text{rx2} \leftarrow \text{sapply(tMeth, function(M) rank(x2, ties.method=M))}\)
\(\text{cbind(x2, rx2)}\)

### ties.method's does not matter w/o ties:

\(\text{rx} \leftarrow \text{sapply(tMeth, function(MM) rank(x, ties.method=MM))}\)
\(\text{stopifnot(all(rx[,1] == rx))}\)

---

**rapply**  
*Recursively Apply a Function to a List*

**Description**

`rapply` is a recursive version of `lapply` with flexibility in how the result is structured (how = "...").

**Usage**

\[
rapply(\text{object}, f, \text{classes} = \text{"ANY"}, \text{deflt} = \text{NULL}, \\
\text{how} = \text{c("unlist", "replace", "list"), ...})
\]

**Arguments**

- `object`  
a list or expression, i.e., "list-like".
- `f`  
a function of one "principal" argument, passing further arguments via ....
- `classes`  
character vector of class names, or "ANY" to match any class.
- `deflt`  
The default result (not used if how = "replace").
- `how`  
character string partially matching the three possibilities given: see ‘Details’.
- ...  
additional arguments passed to the call to `f`.

**Details**

This function has two basic modes. If how = "replace", each element of object which is not itself list-like and has a class included in classes is replaced by the result of applying `f` to the element. Otherwise, with mode how = "list" or how = "unlist", conceptually object is copied, all non-list elements which have a class included in classes are replaced by the result of applying `f` to the element and all others are replaced by `deflt`. Finally, if how = "unlist", `unlist(recursive = TRUE)` is called on the result.

The semantics differ in detail from `lapply`: in particular the arguments are evaluated before calling the C code.

In R 3.5.x and earlier, object was required to be a list, which was not the case for its list-like components.
Value

If `how = "unlist"`, a vector, otherwise “list-like” of similar structure as `object`.

References

(rapply is only described briefly there.)

lapply, dendrapply.

Examples

```r
X <- list(list(a = pi, b = list(c = 1L)), d = "a test")
  # the "identity operation":
  rapply(X, function(x) x, how = "replace") -> X.; stopifnot(identical(X, X.))
  rapply(X, sqrt, classes = "numeric", how = "replace")
  rapply(X, deparse, control = "all") # passing extras. argument of deparse()
  rapply(X, nchar, classes = "character", deflt = NA_integer_, how = "list")
  rapply(X, nchar, classes = "character", how = "unlist")
  rapply(X, log, classes = "numeric", how = "replace", base = 2)
```  
  ```r
  ## with expression() / list():
  E <- expression(list(a = pi, b = expression(c = C1 * C2)), d = "a test")
  LE <- list(expression(a = pi, b = expression(c = C1 * C2)), d = "a test")
  rapply(E, nchar, how="replace") # "expression(c = C1 * C2)" are 23 chars
  rapply(LE, as.character) # a "pi" | b1 "expression" | b2 "C1 * C2" ..
  rapply(LE, nchar)  # (see above)
  stopifnot(exprs = {
    identical(E , rapply(E , identity, how = "replace"))
    identical(LE, rapply(LE, identity, how = "replace"))
  })
```

---

**raw**

### Raw Vectors

**Description**

Creates or tests for objects of type "raw".

**Usage**

```r
raw(length = 0)
as.raw(x)
is.raw(x)
```

**Arguments**

- `length` desired length.
- `x` object to be coerced.
The raw type is intended to hold raw bytes. It is possible to extract subsequences of bytes, and to replace elements (but only by elements of a raw vector). The relational operators (see Comparison, using the numerical order of the byte representation) work, as do the logical operators (see Logic) with a bitwise interpretation.

A raw vector is printed with each byte separately represented as a pair of hex digits. If you want to see a character representation (with escape sequences for non-printing characters) use rawToChar.

Coercion to raw treats the input values as representing small (decimal) integers, so the input is first coerced to integer, and then values which are outside the range \([0 \ldots 255]\) or are NA are set to 0 (the null byte).

as.raw and is.raw are primitive functions.

**Value**

`raw` creates a raw vector of the specified length. Each element of the vector is equal to 0. Raw vectors are used to store fixed-length sequences of bytes.

as.raw attempts to coerce its argument to be of raw type. The (elementwise) answer will be 0 unless the coercion succeeds (or if the original value successfully coerces to 0).

is.raw returns true if and only if `typeof(x) == "raw"`.

**See Also**

`charToRaw`, `rawShift`, etc.

& for bitwise operations on raw vectors.

**Examples**

```r
xx <- raw(2)
x[1] <- as.raw(40) # NB, not just 40.
x[2] <- charToRaw("A")
x  # 28 41 -- raw prints hexadecimals
dput(x)  # as.raw(c(0x28, 0x41))
as.integer(x)  # 40 65

x <- "A test string"
(y <- charToRaw(x))
is.vector(y) # TRUE
rawToChar(y)
is.raw(x)
is.raw(y)
stopifnot(charToRaw("\xa3") == as.raw(0xa3))

isASCII <- function(txt) all(charToRaw(txt) <= as.raw(127))
isASCII(x) # true
isASCII("\xa325.63") # false (in Latin-1, this is an amount in UK pounds)
```
**rawConnection**

---

**Raw Connections**

**Description**

Input and output raw connections.

**Usage**

```r
rawConnection(object, open = "r")
rawConnectionValue(con)
```

**Arguments**

- `object` character or raw vector. A description of the connection. For an input this is an R raw vector object, and for an output connection the name for the connection.
- `open` character. Any of the standard connection open modes.
- `con` An output raw connection.

**Details**

An input raw connection is opened and the raw vector is copied at the time the connection object is created, and `close` destroys the copy.

An output raw connection is opened and creates an R raw vector internally. The raw vector can be retrieved via `rawConnectionValue`.

If a connection is open for both input and output the initial raw vector supplied is copied when the connections is open.

**Value**

For `rawConnection`, a connection object of class "rawConnection" which inherits from class "connection".

For `rawConnectionValue`, a raw vector.

**Note**

As output raw connections keep the internal raw vector up to date call-by-call, they are relatively expensive to use (although over-allocation is used), and it may be better to use an anonymous `file()` connection to collect output.

On (rare) platforms where `vsnprintf` does not return the needed length of output there is a 100,000 character limit on the length of line for output connections: longer lines will be truncated with a warning.

**See Also**

`connections`, `showConnections`. 
Examples

zz <- rawConnection(raw(0), "r") # start with empty raw vector
writeBin(LETTERS, zz)
seek(zz, 0)
readlines(zz) # raw vector has embedded nuls
seek(zz, 0)
writeBin(letters[1:3], zz)
rawConnectionValue(zz)
close(zz)

rawConversion  Convert to or from (Bit/Packed) Raw Vectors

Description

Conversion to and from and manipulation of objects of type "raw", both used as bits or “packed” 8 bits.

Usage

charToRaw(x)
rawToChar(x, multiple = FALSE)

rawShift(x, n)

rawToBits(x)
intToBits(x)
packBits(x, type = c("raw", "integer", "double"))

numToInts(x)
numToBits(x)

Arguments

x          object to be converted or shifted.
multiple   logical: should the conversion be to a single character string or multiple individual characters?
n          the number of bits to shift. Positive numbers shift right and negative numbers shift left; allowed values are -8 . . . 8.
type       the result type, partially matched.

Details

packBits accepts raw, integer or logical inputs, the last two without any NAs.
Note that ‘bytes’ are not necessarily the same as characters, e.g. in UTF-8 locales.
Value

charToRaw converts a length-one character string to raw bytes. It does so without taking into account any declared encoding (see Encoding).

rawToChar converts raw bytes either to a single character string or a character vector of single bytes (with "\n" for \0). (Note that a single character string could contain embedded nulls; only trailing nulls are allowed and will be removed.) In either case it is possible to create a result which is invalid in a multibyte locale, e.g. one using UTF-8. Long vectors are allowed if multiple is true.

rawShift(x, n) shift the bits in x by n positions to the right, see the argument n, above.

rawToBits returns a raw vector of 8 times the length of a raw vector with entries 0 or 1. intToBits returns a raw vector of 32 times the length of an integer vector with entries 0 or 1. (Non-integral numeric values are truncated to integers.) In both cases the unpacking is least-significant bit first.

packBits packs its input (using only the lowest bit for raw or integer vectors) least-significant bit first to a raw, integer or double (“numeric”) vector.

numToInts() and numToBits() split double precision numeric vectors either into two integers each or into 64 bits each, stored as raw.

Examples

x <- "A test string"
(y <- charToRaw(x))
is.vector(y) # TRUE

rawToChar(y)
rawToChar(y, multiple = TRUE)
(xx <- c(y, charToRaw("&"), charToRaw("more")))
rawToChar(xx)

rawShift(y, 1)
rawShift(y, -2)

rawToBits(y)

showBits <- function(r) stats::symnum(as.logical(rawToBits(r)))

z <- as.raw(5)
z ; showBits(z)
showBits(rawShift(z, 1)) # shift to right
showBits(rawShift(z, 2))
showBits(z)
showBits(rawShift(z, -1)) # shift to left
showBits(rawShift(z, -2)) # ..
showBits(rawShift(z, -3)) # shifted off entirely

packBits(as.raw(0:31))
i <- -2:3
stopifnot(exprs = {
    identical(i, packBits(intToBits(i), "integer")),
    identical(packBits(0:31),
        packBits(as.raw(0:31)))
})

str(pB1 <- packBits(intToBits(i)))
data.frame(B = matrix(pB1, nrow=6, byrow=TRUE),
    hex = format(as.hexmode(i)), i)
## Look at internal bit representation of ...

## ... of integers:

```
.Platform $ endian # "little" (typically on all platforms R runs (??))
R <- if(.Platform $ endian == "little") rev else identity
bitI <- function(x) vapply(as.integer(x), function(x) {
  b <- substr(as.character(R(intToBits(x))), 2L, 2L)
  paste0(c(b[1L], " ", b[2:32]), collapse = "")
}, "")
print(bitI(-8:8), width = 35, quote = FALSE)
```

## ... of double precision numbers in format 'sign exp | mantissa'

## where 1 bit sign 1 <=> "-";
## 11 bit exp is the base-2 exponent in 2-complement form
## 52 bit mantissa is without the implicit leading '1'

```
R <- if(.Platform $ endian == "little") rev else identity
## Bit representation [ sign | exponent | mantissa ] of double prec numbers:

bitC <- function(x) noquote(vapply(as.double(x), function(x) {
  b <- substr(as.character(R(numToBits(x))), 2L, 2L)
  paste0(c(b[1L], " ", b[2:12], " | ", b[13:64]), collapse = "")
}, ""))
bitC(17)
bitC(c(-1,0,1))
bitC(2^(-2:5))
bitC(1+2^(-1:53))# from 0.5 converge to 1
```

### numToBits(.) <==> intToBits(numToInts(.)):

d2bI <- function(x) vapply(as.double(x), function(x) intToBits(numToInts(x)), raw(64L))
d2b <- function(x) vapply(as.double(x), function(x) numToBits(x), raw(64L))
set.seed(1)
x <- c(sort(rt(2048, df=1.5)), 2^(-10:10), 1+2^(-1:53))
str(bx <- d2b(x)) # a 64 x 2122 raw matrix
stopifnot( identical(bx, d2bI(x)) )
```

## Show that packBits(*, "double") is the inverse of numToBits():

```
pbx <- apply(bx, 2, packBits, type="double")
stopifnot( identical(pbx, x))
```

---

**RdUtils**

Utilities for Processing Rd Files

**Description**

Utilities for converting files in R documentation (Rd) format to other formats or create indices from them, and for converting documentation in other formats to Rd format.

**Usage**

```
R CMD Rdconv [options] file
R CMD Rd2pdf [options] files
```
Arguments

- **file**: the path to a file to be processed.
- **files**: a list of file names specifying the R documentation sources to use, by either giving the paths to the files, or the path to a directory with the sources of a package.
- **options**: further options to control the processing, or for obtaining information about usage and version of the utility.

Details

R CMD Rdconv converts Rd format to plain text, HTML or LaTeX formats: it can also extract the examples.

R CMD Rd2pdf is the user-level program for producing PDF output from Rd sources. It will make use of the environment variables R_PAPERSIZE (set by R CMD, with a default set when R was installed: values for R_PAPERSIZE are a4, letter, legal and executive) and R_PDFVIEWER (the PDF previewer). Also, Rd2pdf_INPUTENC can be set to inputenx to make use of the LaTeX package of that name rather than inputenc: this might be needed for better support of the UTF-8 encoding.

R CMD Rd2pdf calls tools::texi2pdf to produce its PDF file: see its help for the possibilities for the texi2dvi command which that function uses (and which can be overridden by setting environment variable R_TEXI2DVICMD).

Use R CMD foo --help to obtain usage information on utility foo.

---

**readBin**  
 Transfer Binary Data To and From Connections

**Description**

Read binary data from or write binary data to a connection or raw vector.

**Usage**

```r
readBin(con, what, n = 1L, size = NA_integer_, signed = TRUE,
         endian = .Platform$endian)
```

```r
writeBin(object, con, size = NA_integer_,
         endian = .Platform$endian, useBytes = FALSE)
```

**Arguments**

- **con**: A connection object or a character string naming a file or a raw vector.
- **what**: Either an object whose mode will give the mode of the vector to be read, or a character vector of length one describing the mode: one of "numeric", "double", "integer", "int", "logical", "complex", "character", "raw".
- **n**: numeric. The (maximal) number of records to be read. You can use an over-estimate here, but not too large as storage is reserved for n items.
size  integer. The number of bytes per element in the byte stream. The default, NA_integer_, uses the natural size. Size changing is not supported for raw and complex vectors.

signed logical. Only used for integers of sizes 1 and 2, when it determines if the quantity on file should be regarded as a signed or unsigned integer.

download The endian-ness ("big" or "little") of the target system for the file. Using "swap" will force swapping endian-ness.

object An R object to be written to the connection.

useBytes See writeLines.

Details

These functions can only be used with binary-mode connections. If con is a character string, the functions call file to obtain a binary-mode file connection which is opened for the duration of the function call.

If the connection is open it is read/written from its current position. If it is not open, it is opened for the duration of the call in an appropriate mode (binary read or write) and then closed again. An open connection must be in binary mode.

If readBin is called with con a raw vector, the data in the vector is used as input. If writeBin is called with con a raw vector, it is just an indication that a raw vector should be returned.

If size is specified and not the natural size of the object, each element of the vector is coerced to an appropriate type before being written or as it is read. Possible sizes are 1, 2, 4 and possibly 8 for integer or logical vectors, and 4, 8 and possibly 12/16 for numeric vectors. (Note that coercion occurs as signed types except if signed = FALSE when reading integers of sizes 1 and 2.) Changing sizes is unlikely to preserve NAs, and the extended precision sizes are unlikely to be portable across platforms.

readBin and writeBin read and write C-style zero-terminated character strings. Input strings are limited to 10000 characters. readChar and writeChar can be used to read and write fixed-length strings. No check is made that the string is valid in the current locale’s encoding.

Handling R’s missing and special (Inf, -Inf and NaN) values is discussed in the ‘R Data Import/Export’ manual.

Only $2^{31} - 1$ bytes can be written in a single call (and that is the maximum capacity of a raw vector on 32-bit platforms).

‘Endian-ness’ is relevant for size > 1, and should always be set for portable code (the default is only appropriate when writing and then reading files on the same platform).

Value

For readBin, a vector of appropriate mode and length the number of items read (which might be less than n).

For writeBin, a raw vector (if con is a raw vector) or invisibly NULL.

Note

Integer read/writes of size 8 will be available if either C type long is of size 8 bytes or C type long long exists and is of size 8 bytes.

Real read/writes of size sizeof(long double) (usually 12 or 16 bytes) will be available only if that type is available and different from double.
If `readBin(what = character())` is used incorrectly on a file which does not contain C-style character strings, warnings (usually many) are given. From a file or connection, the input will be broken into pieces of length 10000 with any final part being discarded.

**See Also**

The 'R Data Import/Export' manual.  
`readChar` to read/write fixed-length strings.  
`connections, readLines, writeLines`.  
`.Machine` for the sizes of long, long long and long double.

**Examples**

```r
zzfil <- tempfile("testbin")
zz <- file(zzfil, "wb")
writeBin(1:10, zz)
writeBin(pi, zz, endian = "swap")
writeBin(pi^2, zz, size = 4, endian = "swap")
writeBin(pi+3l, zz)
writeBin("A test of a connection", zz)
z <- paste("A very long string", 1:100, collapse = " + ")
writeln(z, zz)
if(.Machine$sizeof.long == 8 || .Machine$sizeof.longlong == 8)
  writeln(as.integer(5^(1:10)), zz, size = 8)
if((s <- .Machine$sizeof.longdouble) > 8)
  writeln((pi/3)^(1:10), zz, size = s)
close(zz)

zz <- file(zzfil, "rb")
readBin(zz, integer(), 4)
readBin(zz, integer(), 6)
readBin(zz, numeric(), 1, endian = "swap")
readBin(zz, numeric(), size = 4)
readBin(zz, numeric(), size = 4, endian = "swap")
readBin(zz, complex(), 1)
readBin(zz, character(), 1)
z2 <- readBin(zz, character(), 1)
if(.Machine$sizeof.long == 8 || .Machine$sizeof.longlong == 8)
  readBin(zz, integer(), 10, size = 8)
if((s <- .Machine$sizeof.longdouble) > 8)
  readBin(zz, numeric(), 10, size = s)
close(zz)
unlink(zzfil)
stopifnot(z2 == z)
```

```r
## signed vs unsigned ints
zzfil <- tempfile("testbin")
zz <- file(zzfil, "wb")
x <- as.integer(seq(0, 255, 32))
writeBin(x, zz, size = 1)
writeBin(x, zz, size = 1)
x <- as.integer(seq(0, 60000, 10000))
writeBin(x, zz, size = 2)
writeBin(x, zz, size = 2)
close(zz)
```
zz <- file(zzfil, "rb")
readBin(zz, integer(), 8, size = 1)
readBin(zz, integer(), 8, size = 1, signed = FALSE)
readBin(zz, integer(), 7, size = 2)
readBin(zz, integer(), 7, size = 2, signed = FALSE)
close(zz)
unlink(zzfil)

## use of raw
z <- writeBin(pi^{1:5}, raw(), size = 4)
readBin(z, numeric(), 5, size = 4)
z <- writeBin(c("a", "test", "of", "character"), raw())
readBin(z, character(), 4)

---

### readChar

**Transfer Character Strings To and From Connections**

#### Description

Transfer character strings to and from connections, without assuming they are null-terminated on the connection.

#### Usage

```r
readChar(con, nchars, useBytes = FALSE)
writeChar(object, con, nchars = nchar(object, type = "chars"),
          eos = ",", useBytes = FALSE)
```

#### Arguments

- **con**
  A connection object, or a character string naming a file, or a raw vector.
- **nchars**
  integer vector, giving the lengths in characters of (unterminated) character strings to be read or written. Elements must be >= 0 and not NA.
- **useBytes**
  logical: For readChar, should nchars be regarded as a number of bytes not characters in a multi-byte locale? For writeChar, see writeLines.
- **object**
  A character vector to be written to the connection, at least as long as nchars.
- **eos**
  ‘end of string’: character string. The terminator to be written after each string, followed by an ASCII null; use NULL for no terminator at all.

#### Details

These functions complement readBin and writeBin which read and write C-style zero-terminated character strings. They are for strings of known length, and can optionally write an end-of-string mark. They are intended only for character strings valid in the current locale.

These functions are intended to be used with binary-mode connections. If con is a character string, the functions call file to obtain a binary-mode file connection which is opened for the duration of the function call.

If the connection is open it is read/written from its current position. If it is not open, it is opened for the duration of the call in an appropriate mode (binary read or write) and then closed again. An open connection must be in binary mode.
If `readChar` is called with `con` a raw vector, the data in the vector is used as input. If `writeChar` is called with `con` a raw vector, it is just an indication that a raw vector should be returned.

Character strings containing ASCII nul(s) will be read correctly by `readChar` but truncated at the first nul with a warning.

If the character length requested for `readChar` is longer than the data available on the connection, what is available is returned. For `writeChar` if too many characters are requested the output is zero-padded, with a warning.

Missing strings are written as `NA`.

**Value**

For `readChar`, a character vector of length the number of items read (which might be less than `length(nchars)`).

For `writeChar`, a raw vector (if `con` is a raw vector) or invisibly `NULL`.

**Note**

Earlier versions of R allowed embedded nul bytes within character strings, but not R >= 2.8.0. `readChar` was commonly used to read fixed-size zero-padded byte fields for which `readBin` was unsuitable. `readChar` can still be used for such fields if there are no embedded nuls: otherwise `readBin(what = "raw")` provides an alternative.

`nchars` will be interpreted in bytes not characters in a non-UTF-8 multi-byte locale, with a warning.

There is little validity checking of UTF-8 reads.

Using these functions on a text-mode connection may work but should not be mixed with text-mode access to the connection, especially if the connection was opened with an encoding argument.

**See Also**

The ‘R Data Import/Export’ manual.

`connections, readLines, writeLines, readBin`

**Examples**

```r
## test fixed-length strings
zzfil <- tempfile("testchar")
zz <- file(zzfil, "wb")
x <- c("a", "this will be truncated", "abc")
nc <- c(3, 10, 3)
writeChar(x, zz, nc, eos = NULL)
writeChar(x, zz, eos = "\r\n")
close(zz)

zz <- file(zzfil, "rb")
readChar(zz, nc)
readChar(zz, nchar(x)+3) # need to read the terminator explicitly
close(zz)
unlink(zzfil)
```
Readline

Read a Line from the Terminal

Description

Readline reads a line from the terminal (in interactive use).

Usage

`readline(prompt = "")`

Arguments

- `prompt`: the string printed when prompting the user for input. Should usually end with a space " ".

Details

The prompt string will be truncated to a maximum allowed length, normally 256 chars (but can be changed in the source code).

This can only be used in an interactive session.

Value

A character vector of length one. Both leading and trailing spaces and tabs are stripped from the result.

In non-interactive use the result is as if the response was RETURN and the value is " ".

See Also

- `readLines` for reading text lines from connections, including files.

Examples

```r
fun <- function() {
  ANSWER <- readline("Are you a satisfied R user? ")
  # a better version would check the answer less cursorily, and
  # perhaps re-prompt
  if (substr(ANSWER, 1, 1) == "n")
    cat("This is impossible. YOU LIED!\n")
  else
    cat("I knew it.\n")
}
if(interactive()) fun()
```
Description

Read some or all text lines from a connection.

Usage

```r
readLines(con = stdin(), n = -1L, ok = TRUE, warn = TRUE,
encoding = "unknown", skipNul = FALSE)
```

Arguments

- `con` a connection object or a character string.
- `n` integer. The (maximal) number of lines to read. Negative values indicate that one should read up to the end of input on the connection.
- `ok` logical. Is it OK to reach the end of the connection before `n > 0` lines are read? If not, an error will be generated.
- `warn` logical. Warn if a text file is missing a final EOL or if there are embedded nuls in the file.
- `encoding` encoding to be assumed for input strings. It is used to mark character strings as known to be in Latin-1 or UTF-8: it is not used to re-encode the input. To do the latter, specify the encoding as part of the connection `con` or via `options(encoding=)`: see the examples.
- `skipNul` logical: should nuls be skipped?

Details

If the `con` is a character string, the function calls `file` to obtain a file connection which is opened for the duration of the function call. This can be a compressed file.

If the connection is open it is read from its current position. If it is not open, it is opened in "rt" mode for the duration of the call and then closed (but not destroyed; one must call `close` to do that).

If the final line is incomplete (no final EOL marker) the behaviour depends on whether the connection is blocking or not. For a non-blocking text-mode connection the incomplete line is pushed back, silently. For all other connections the line will be accepted, with a warning. Whatever mode the connection is opened in, any of LF, CRLF or CR will be accepted as the EOL marker for a line. Embedded nuls in the input stream will terminate the line currently being read, with a warning (unless `skipNul` = TRUE or `warn` = FALSE).

If `con` is a not-already-open connection with a non-default encoding argument, the text is converted to UTF-8 and declared as such (and the encoding argument to `readLines` is ignored). See the examples.

Value

A character vector of length the number of lines read.

The elements of the result have a declared encoding if `encoding` is "latin1" or "UTF-8",
Note

The default connection, stdin, may be different from con = "stdin": see file.

See Also

connections, writeLines, readBin, scan

Examples

```r
fil <- tempfile(fileext = ".data")
cat("TITLE extra line", "2 3 5 7", ",", "11 13 17", file = fil, sep = "\n")
readlines(fil, n = -1)
unlink(fil) # tidy up

## difference in blocking
fil <- tempfile("test")
cat("123\nabc", file = fil)
readlines(fil) # line with a warning

con <- file(fil, "r", blocking = FALSE)
readlines(con) # empty
cat(" def\n", file = fil, append = TRUE)
readlines(con) # gets both
close(con)

unlink(fil) # tidy up

## Not run:
# read a 'Windows Unicode' file
A <- readLines(con <- file("Unicode.txt", encoding = "UCS-2LE"))
close()
unique(Encoding(A)) # will most likely be UTF-8

## End(Not run)
```

readRDS

Serialization Interface for Single Objects

Description

Functions to write a single R object to a file, and to restore it.

Usage

```r
saveRDS(object, file = "", ascii = FALSE, version = NULL, 
        compress = TRUE, refhook = NULL)

readRDS(file, refhook = NULL)
infoRDS(file)
```
readRDS

Arguments

object  \( \mathbb{R} \) object to serialize.
file  a connection or the name of the file where the \( \mathbb{R} \) object is saved to or read from.
ascii  a logical. If TRUE or NA, an ASCII representation is written; otherwise (default), a binary one is used. See the comments in the help for \texttt{save}.
version  the workspace format version to use. NULL specifies the current default version (3). The only other supported value is 2, the default from \texttt{R 1.4.0} to \texttt{R 3.5.0}.
compress  a logical specifying whether saving to a named file is to use "gzip" compression, or one of "gzip", "bzip2" or "xz" to indicate the type of compression to be used. Ignored if \texttt{file} is a connection.
refhook  a hook function for handling reference objects.

Details

\texttt{saveRDS} and \texttt{readRDS} provide the means to save a single \( \mathbb{R} \) object to a connection (typically a file) and to restore the object, quite possibly under a different name. This differs from \texttt{save} and \texttt{load}, which save and restore one or more named objects into an environment. They are widely used by \texttt{R} itself, for example to store metadata for a package and to store the \texttt{help.search} databases: the "\.rds" file extension is most often used.

Functions \texttt{serialize} and \texttt{unserialize} provide a slightly lower-level interface to serialization: objects serialized to a connection by \texttt{serialize} can be read back by \texttt{readRDS} and conversely.

Function \texttt{infoRDS} retrieves meta-data about serialization produced by \texttt{saveRDS} or \texttt{serialize}. \texttt{infoRDS} cannot be used to detect whether a file is a serialization nor whether it is valid.

All of these interfaces use the same serialization format, but \texttt{save} writes a single line header (typically "RDXs\n") before the serialization of a single object (a pairlist of all the objects to be saved).

If \texttt{file} is a file name, it is opened by \texttt{gzfile} except for \texttt{save(compress = FALSE)} which uses \texttt{file}. Only for the exception are marked encodings of \texttt{file} which cannot be translated to the native encoding handled on Windows.

Compression is handled by the connection opened when \texttt{file} is a file name, so is only possible when \texttt{file} is a connection if handled by the connection. So e.g. \texttt{url} connections will need to be wrapped in a call to \texttt{gzcon}.

If a connection is supplied it will be opened (in binary mode) for the duration of the function if not already open: if it is already open it must be in binary mode for \texttt{saveRDS(ascii = FALSE)} or to read non-ASCII saves.

Value

For \texttt{readRDS}, an \( \mathbb{R} \) object.
For \texttt{saveRDS}, NULL invisibly.
For \texttt{infoRDS}, an \( \mathbb{R} \) list with elements \texttt{version} (version number, currently 2 or 3), \texttt{writer_version} (version of \( \mathbb{R} \) that produced the serialization), \texttt{min_reader_version} (minimum version of \( \mathbb{R} \) that can read the serialization), \texttt{format} (data representation) and \texttt{native_encoding} (native encoding of the session that produced the serialization, available since version 3). The data representation is given as "xdr" for big-endian binary representation, "ascii" for ASCII representation (produced via \texttt{ascii = TRUE} or \texttt{ascii = NA}) or "binary" (binary representation with native 'endian-ness' which can be produced by \texttt{serialize}).
See Also

serialize, save and load.

The ‘R Internals’ manual for details of the format used.

Examples

```r
fil <- tempfile("women", fileext = ".rds")
## save a single object to file
saveRDS(women, fil)
## restore it under a different name
women2 <- readRDS(fil)
identical(women, women2)
## or examine the object via a connection, which will be opened as needed.
con <- gzfile(fil)
readRDS(con)
close(con)
## Less convenient ways to restore the object
## which demonstrate compatibility with unserialize()
con <- gzfile(fil, "rb")
identical(unserialize(con), women)
close(con)
con <- gzfile(fil, "rb")
w <- readBin(con, "raw", n = 1e4) # size is a guess
close(con)
identical(unserialize(w), women)
## Format compatibility with serialize():
fil2 <- tempfile("women")
con <- file(fil2, "w")
serialize(women, con) # ASCII, uncompressed
close(con)
identical(women, readRDS(fil2))
fil3 <- tempfile("women")
con <- bzfile(fil3, "w")
serialize(women, con) # binary, bzip2-compressed
close(con)
identical(women, readRDS(fil3))

unlink(c(fil, fil2, fil3))
```

readRenvion

Set Environment Variables from a File

Description

Read as file such as `.Renviron` or `Renviron.site` in the format described in the help for Startup, and set environment variables as defined in the file.

Usage

readRenvion(path)
Recall

Arguments

path A length-one character vector giving the path to the file. Tilde-expansion is performed where supported.

Value

Scalar logical indicating if the file was read successfully. Returned invisibly. If the file cannot be opened for reading, a warning is given.

See Also

Startup for the file format.

Examples

## Not run:
## re-read a startup file (or read it in a vanilla session)
readRenviron("~/.Renviron")
## End(Not run)

Recall Recursive Calling

Description

Recall is used as a placeholder for the name of the function in which it is called. It allows the definition of recursive functions which still work after being renamed, see example below.

Usage

Recall(...)

Arguments

... all the arguments to be passed.

Note

Recall will not work correctly when passed as a function argument, e.g. to the apply family of functions.

See Also

do.call and call.

local for another way to write anonymous recursive functions.
Examples

```r
## A trivial (but inefficient!) example:
fib <- function(n)
  if(n<=2) { if(n>=0) 1 else 0 } else Recall(n-1) + Recall(n-2)
fibonacci <- fib; rm(fib)
## renaming wouldn't work without Recall
fibonacci(10) # 55
```

---

**reg.finalizer**

Finalization of Objects

**Description**

Registers an R function to be called upon garbage collection of object or (optionally) at the end of an R session.

**Usage**

```r
reg.finalizer(e, f, onexit = FALSE)
```

**Arguments**

- `e`: Object to finalize. Must be an environment or an external pointer.
- `f`: Function to call on finalization. Must accept a single argument, which will be the object to finalize.
- `onexit`: logical: should the finalizer be run if the object is still uncollected at the end of the R session?

**Details**

The main purpose of this function is to allow objects that refer to external items (a temporary file, say) to perform cleanup actions when they are no longer referenced from within R. This only makes sense for objects that are never copied on assignment, hence the restriction to environments and external pointers.

*Inter alia*, it provides a way to program code to be run at the end of an R session without manipulating `.Last`. For use in a package, it is often a good idea to set a finalizer on an object in the namespace: then it will be called at the end of the session, or soon after the namespace is unloaded if that is done during the session.

**Value**

`NULL`.

**Note**

R’s interpreter is not re-entrant and the finalizer could be run in the middle of a computation. So there are many functions which it is potentially unsafe to call from `f`: one example which caused trouble is `options`. Finalizers are scheduled at garbage collection but only run at a relatively safe time thereafter.
regex

See Also

gc and Memory for garbage collection and memory management.

Examples

\begin{verbatim}
f <- function(e) print("cleaning....")
g <- function(x){ e <- environment(); reg.finalizer(e, f) }
g()
invisible(gc()) # trigger cleanup
\end{verbatim}

Description

This help page documents the regular expression patterns supported by \texttt{grep} and related functions \texttt{grepl, regexpr, gregexpr, sub and gsub}, as well as by \texttt{strsplit}.

Details

A ‘regular expression’ is a pattern that describes a set of strings. Two types of regular expressions are used in \texttt{R}, extended regular expressions (the default) and Perl-like regular expressions used by \texttt{perl = TRUE}. There is also \texttt{fixed = TRUE} which can be considered to use a literal regular expression. Other functions which use regular expressions (often via the use of \texttt{grep}) include \texttt{apropos, browseEnv, help.search, list.files} and \texttt{ls}. These will all use extended regular expressions.

Patterns are described here as they would be printed by \texttt{cat}: (do remember that backslashes need to be doubled when entering \texttt{R} character strings, e.g. from the keyboard).

Long regular expression patterns may or may not be accepted: the POSIX standard only requires up to 256 bytes.

Extended Regular Expressions

This section covers the regular expressions allowed in the default mode of \texttt{grep}, \texttt{grepl, regexpr, gregexpr, sub}, \texttt{gsub, regexec} and \texttt{strsplit}. They use an implementation of the POSIX 1003.2 standard: that allows some scope for interpretation and the interpretations here are those currently used by \texttt{R}. The implementation supports some extensions to the standard.

Regular expressions are constructed analogously to arithmetic expressions, by using various operators to combine smaller expressions. The whole expression matches zero or more characters (read ‘character’ as ‘byte’ if \texttt{useBytes = TRUE}).

The fundamental building blocks are the regular expressions that match a single character. Most characters, including all letters and digits, are regular expressions that match themselves. Any metacharacter with special meaning may be quoted by preceding it with a backslash. The metacharacters in extended regular expressions are ‘. \ |
( ) \[ { ^ $ * + ?’, but note that whether these have a special meaning depends on the context.

Escaping non-metacharacters with a backslash is implementation-dependent. The current implementation interprets ‘\a’ as ‘BEL’, ‘\e’ as ‘ESC’, ‘\f’ as ‘FF’, ‘\n’ as ‘LF’, ‘\r’ as ‘CR’ and ‘\t’ as ‘TAB’. (Note that these will be interpreted by \texttt{R}’s parser in literal character strings.)

A character class is a list of characters enclosed between ‘[’ and ‘]’ which matches any single character in that list; unless the first character of the list is the caret ‘\^’, when it matches any
character not in the list. For example, the regular expression `'[0123456789]'` matches any single digit, and `'[\^abc]'` matches anything except the characters ‘a’, ‘b’ or ‘c’. A range of characters may be specified by giving the first and last characters, separated by a hyphen. (Because their interpretation is locale- and implementation-dependent, character ranges are best avoided. Some but not all implementations include both cases in ranges when doing caseless matching.) The only portable way to specify all ASCII letters is to list them all as the character class `'[ABCDEFGHIJKLMNOPQRSTUVWXYZabcdefghijklmnopqrstuvwxyz]'`. (The current implementation uses numerical order of the encoding, normally a single-byte encoding or Unicode points.)

Certain named classes of characters are predefined. Their interpretation depends on the locale (see locales); the interpretation below is that of the POSIX locale.

`'[:alnum:]'` Alphanumeric characters: `':[alpha:]'` and `':[digit:]'`.

`'[:alpha:]'` Alphabetic characters: `':[lower:]'` and `':[upper:]'`.

`'[:blank:]'` Blank characters: space and tab, and possibly other locale-dependent characters such as non-breaking space.

`'[:cntrl:]'` Control characters. In ASCII, these characters have octal codes 000 through 037, and 177 (DEL). In another character set, these are the equivalent characters, if any.

`'[:digit:]'` Digits: ‘0 1 2 3 4 5 6 7 8 9’.

`'[:graph:]'` Graphical characters: `':[alnum:]'` and `':[punct:]'`.

`'[:lower:]'` Lower-case letters in the current locale.

`'[:print:]'` Printable characters: `':[alnum:]',''[punct:]'` and space.

`'[:punct:]'` Punctuation characters:

`'[:space:]'` Space characters: tab, newline, vertical tab, form feed, carriage return, space and possibly other locale-dependent characters.

`'[:upper:]'` Upper-case letters in the current locale.

`'[:xdigit:]'` Hexadecimal digits:

For example, `'[[:alnum:]]'` means `[0-9A-Za-z]`, except the latter depends upon the locale and the character encoding, whereas the former is independent of locale and character set. (Note that the brackets in these class names are part of the symbolic names, and must be included in addition to the brackets delimiting the bracket list.) Most metacharacters lose their special meaning inside a character class. To include a literal ‘]’, place it first in the list. Similarly, to include a literal ‘^’, place it anywhere but first. Finally, to include a literal ‘\’, place it first or last (or, for perl = TRUE only, precede it by a backslash). (Only ‘^ -\ ’]’ are special inside character classes.)

The period ‘.’ matches any single character. The symbol ‘\w’ matches a ‘word’ character (a synonym for `[[:alnum:][:\ ]], an extension) and ‘\W’ is its negation (‘[^[[:alnum:][:\ ]]]’). Symbols ‘\d’, ‘\s’, ‘\D’ and ‘\S’ denote the digit and space classes and their negations (these are all extensions).

The caret ‘^’ and the dollar sign ‘$’ are metacharacters that respectively match the empty string at the beginning and end of a line. The symbols ‘\<’ and ‘\>’ match the empty string at the beginning and end of a word. The symbol ‘\b’ matches the empty string at either edge of a word, and ‘\B’ matches the empty string provided it is not at an edge of a word. (The interpretation of ‘word’ depends on the locale and implementation: these are all extensions.)

A regular expression may be followed by one of several repetition quantifiers:

‘?’ The preceding item is optional and will be matched at most once.
‘*’ The preceding item will be matched zero or more times.

‘+’ The preceding item will be matched one or more times.

‘{n}’ The preceding item is matched exactly n times.

‘{n,}’ The preceding item is matched at least n times, but not more than m times.

By default repetition is greedy, so the maximal possible number of repeats is used. This can be changed to ‘minimal’ by appending ? to the quantifier. (There are further quantifiers that allow approximate matching: see the TRE documentation.)

Regular expressions may be concatenated; the resulting regular expression matches any string formed by concatenating the substrings that match the concatenated subexpressions.

Two regular expressions may be joined by the infix operator ‘|’; the resulting regular expression matches any string matching either subexpression. For example, ‘abba|cde’ matches either the string abba or the string cde. Note that alternation does not work inside character classes, where ‘|’ has its literal meaning.

Repetition takes precedence over concatenation, which in turn takes precedence over alternation. A whole subexpression may be enclosed in parentheses to override these precedence rules.

The backreference ‘\N’, where ‘N = 1 . . . 9’, matches the substring previously matched by the Nth parenthesized subexpression of the regular expression. (This is an extension for extended regular expressions: POSIX defines them only for basic ones.)

**Perl-like Regular Expressions**

The perl = TRUE argument to grep, regexpr, gregexpr, sub, gsub and strsplit switches to the PCRE library that implements regular expression pattern matching using the same syntax and semantics as Perl 5.x, with just a few differences.

For complete details please consult the man pages for PCRE, especially man pcrepattern and man pcreapi, on your system or from the sources at https://www.pcre.org. (The version in use can be found by calling extSoftVersion. It need not be the version described in the system’s man page. PCRE1 (reported as version < 10.00 by extSoftVersion) has been feature-frozen for some time (essentially 2012), the man pages at https://www.pcre.org/original/doc/html/ should be a good match. PCRE2 (PCRE version >= 10.00) has man pages at https://www.pcre.org/current/doc/html/).

Perl regular expressions can be computed byte-by-byte or (UTF-8) character-by-character: the latter is used in all multibyte locales and if any of the inputs are marked as UTF-8 (see Encoding).

All the regular expressions described for extended regular expressions are accepted except ‘\<’ and ‘\>’: in Perl all backslashed metacharacters are alphanumeric and backslashed symbols always are interpreted as a literal character. ‘{’ is not special if it would be the start of an invalid interval specification. There can be more than 9 backreferences (but the replacement in sub can only refer to the first 9).

Character ranges are interpreted in the numerical order of the characters, either as bytes in a single-byte locale or as Unicode code points in UTF-8 mode. So in either case ‘[A-Za-z]’ specifies the set of ASCII letters.

In UTF-8 mode the named character classes only match ASCII characters: see ‘\p’ below for an alternative.

The construct ‘(?..?)’ is used for Perl extensions in a variety of ways depending on what immediately follows the ‘?’.

Perl-like matching can work in several modes, set by the options ‘(?i)’ (caseless, equivalent to Perl’s ‘/i’), ‘(?m)’ (multiline, equivalent to Perl’s ‘/m’), ‘(?s)’ (single line, so a dot matches
all characters, even new lines: equivalent to Perl’s ‘/s’ and ‘(?x)’ (extended, whitespace data
characters are ignored unless escaped and comments are allowed: equivalent to Perl’s ‘/x’). These
can be concatenated, so for example, ‘(?im)’ sets caseless multiline matching. It is also possible
to unset these options by preceding the letter with a hyphen, and to combine setting and unsetting
such as ‘(?im-sx)’. These settings can be applied within patterns, and then apply to the remainder
of the pattern. Additional options not in Perl include ‘(?u)’ to set ‘ungreedy’ mode (so matching
is minimal unless ‘?’ is used as part of the repetition quantifier, when it is greedy). Initially none of
these options are set.

If you want to remove the special meaning from a sequence of characters, you can do so by putting
them between ‘\Q’ and ‘\E’. This is different from Perl in that ‘$’ and ‘@’ are handled as literals in
‘\Q...\E’ sequences in PCRE, whereas in Perl, ‘$’ and ‘@’ cause variable interpolation.

The escape sequences ‘\d’, ‘\s’ and ‘\w’ represent any decimal digit, space character and ‘word’
character (letter, digit or underscore in the current locale: in UTF-8 mode only ASCII letters and
digits are considered) respectively, and their upper-case versions represent their negation. Vertical
tab was not regarded as a space character in a C locale before PCRE 8.34. Sequences ‘\h’, ‘\w’,
‘\H’ and ‘\V’ match horizontal and vertical space or the negation. (In UTF-8 mode, these do match
non-ASCII Unicode code points.)

There are additional escape sequences: ‘\cx’ is ‘cnt\{1-x\}’ for any ‘x’, ‘\ddd’ is the octal character
(for up to three digits unless interpretable as a backreference, as ‘\1’ to ‘\7’ always are), and
‘\xhh’ specifies a character by two hex digits. In a UTF-8 locale, ‘\x{h...}’ specifies a Unicode
code point by one or more hex digits. (Note that some of these will be interpreted by R’s parser in
literal character strings.)

Outside a character class, ‘\A’ matches at the start of a subject (even in multiline mode, unlike ‘^’),
‘\Z’ matches at the end of a subject or before a newline at the end, ‘\Z’ matches only at end of
a subject, and ‘\G’ matches at first matching position in a subject (which is subtly different from
Perl’s end of the previous match). ‘\C’ matches a single byte, including a newline, but its use is
warned against. In UTF-8 mode, ‘\R’ matches any Unicode newline character (not just CR), and
‘\X’ matches any number of Unicode characters that form an extended Unicode sequence. ‘\X’,
‘\R’ and ‘\B’ cannot be used inside a character class (with PCRE1, they are treated as characters
‘X’, ‘R’ and ‘B’; with PCRE2 they cause an error).

A hyphen (minus) inside a character class is treated as a range, unless it is first or last character
in the class definition. It can be quoted to represent the hyphen literal (‘\-’). PCRE1 allows an
unquoted hyphen at some other locations inside a character class where it cannot represent a valid
range, but PCRE2 reports an error in such cases.

In UTF-8 mode, some Unicode properties may be supported via ‘\p{xx}’ and ‘\P{xx}’ which match
characters with and without property ‘xx’ respectively. For a list of supported properties see
the PCRE documentation, but for example ‘Lu’ is ‘upper case letter’ and ‘Sc’ is ‘currency symbol’.
(This support depends on the PCRE library being compiled with ‘Unicode property support’ which
can be checked via pcre_config. PCRE2 when compiled with Unicode support always supports
also Unicode properties.)

The sequence ‘(?#’ marks the start of a comment which continues up to the next closing parenthesis.
Nested parentheses are not permitted. The characters that make up a comment play no part at all in
the pattern matching.

If the extended option is set, an unescaped ‘#’ character outside a character class introduces a
comment that continues up to the next newline character in the pattern.

The pattern ‘(?:...’ groups characters just as parentheses do but does not make a backreference.
Patterns ‘(??...)’ and ‘(?!...)’ are zero-width positive and negative lookahead assertions: they
match if an attempt to match the ... forward from the current position would succeed (or not), but
use up no characters in the string being processed. Patterns ‘(?:<=...)’ and ‘(?<!...)’ are the
lookbehind equivalents: they do not allow repetition quantifiers nor ‘\C’ in ...
regexp and gregexpr support ‘named capture’. If groups are named, e.g., "(?<first>[A-Z][a-z]+)" then the positions of the matches are also returned by name. (Named backreferences are not supported by sub.)

Atomic grouping, possessive qualifiers and conditional and recursive patterns are not covered here.

### regmatches

**Extract or Replace Matched Substrings**

**Description**

Extract or replace matched substrings from match data obtained by `regexp`, `gregexpr` or `regexec`.

**Usage**

```r
regmatches(x, m, invert = FALSE)
regmatches(x, m, invert = FALSE) <- value
```

**Arguments**

- `x` a character vector
- `m` an object with match data
- `invert` a logical: if TRUE, extract or replace the non-matched substrings.
- `value` an object with suitable replacement values for the matched or non-matched substrings (see Details).

**Details**

If `invert` is FALSE (default), `regmatches` extracts the matched substrings as specified by the match data. For vector match data (as obtained from `regexp`), empty matches are dropped; for list match data, empty matches give empty components (zero-length character vectors).

If `invert` is TRUE, `regmatches` extracts the non-matched substrings, i.e., the strings are split according to the matches similar to `strsplit` (for vector match data, at most a single split is performed).

If `invert` is NA, `regmatches` extracts both non-matched and matched substrings, always starting and ending with a non-match (empty if the match occurred at the beginning or the end, respectively).
Note that the match data can be obtained from regular expression matching on a modified version of x with the same numbers of characters.

The replacement function can be used for replacing the matched or non-matched substrings. For vector match data, if invert is FALSE, value should be a character vector with length the number of matched elements in m. Otherwise, it should be a list of character vectors with the same length as m, each as long as the number of replacements needed. Replacement coerces values to character or list and generously recycles values as needed. Missing replacement values are not allowed.

**Value**

For regmatches, a character vector with the matched substrings if m is a vector and invert is FALSE. Otherwise, a list with the matched or/and non-matched substrings.

For regmatches<-, the updated character vector.

**Examples**

```r
x <- c("A and B", "A, B and C", "A, B, C and D", "foobar")
pattern <- "\[[[:space:]]*\]\(,|\sand\)[[:space:]]"
## Match data from regexpr()
m <- regexpr(pattern, x)
regmatches(x, m)
regmatches(x, m, invert = TRUE)
## Match data from gregexpr()
m <- gregexpr(pattern, x)
regmatches(x, m)
regmatches(x, m, invert = TRUE)

## Consider
x <- "John (fishing, hunting), Paul (hiking, biking)"
## Suppose we want to split at the comma (plus spaces) between the
## persons, but not at the commas in the parenthesized hobby lists.
## One idea is to "blank out" the parenthesized parts to match the
## parts to be used for splitting, and extract the persons as the
## non-matched parts.
## First, match the parenthesized hobby lists.
m <- gregexpr("\([^(]*\)\)\", x)
## Create blank strings with given numbers of characters.
blanks <- function(n) strrep(" ", n)
## Create a copy of x with the parenthesized parts blanked out.
s <- x
regmatches(s, m) <- Map(blanks, lapply(regmatches(s, m), nchar))
s
## Compute the positions of the split matches (note that we cannot call
## strsplit() on x with match data from s).
m <- gregexpr("\", x", s)
## And finally extract the non-matched parts.
regmatches(x, m, invert = TRUE)
```

---

**remove**

Remove Objects from a Specified Environment
remove

Description

remove and \texttt{rm} can be used to remove objects. These can be specified successively as character strings, or in the character vector \texttt{list}, or through a combination of both. All objects thus specified will be removed.

If \texttt{envir} is \texttt{NULL} then the currently active environment is searched first.

If \texttt{inherits} is \texttt{TRUE} then parents of the supplied directory are searched until a variable with the given name is encountered. A warning is printed for each variable that is not found.

Usage

\begin{verbatim}
remove(...) list = character(), pos = -1, 
\text{envir} = \text{as.environment}(\text{pos}), \text{inherits} = \text{FALSE})
\end{verbatim}

\begin{verbatim}
rm (... list = character(), pos = -1, 
\text{envir} = \text{as.environment}(\text{pos}), \text{inherits} = \text{FALSE})
\end{verbatim}

Arguments

\begin{itemize}
\item \texttt{...} the objects to be removed, as names (unquoted) or character strings (quoted).
\item \texttt{list} a character vector naming objects to be removed.
\item \texttt{pos} where to do the removal. By default, uses the current environment. See ‘details’ for other possibilities.
\item \texttt{envir} the \texttt{environment} to use. See ‘details’.
\item \texttt{inherits} should the enclosing frames of the environment be inspected?
\end{itemize}

Details

The \texttt{pos} argument can specify the environment from which to remove the objects in any of several ways: as an integer (the position in the \texttt{search} list); as the character string name of an element in the \texttt{search} list; or as an \texttt{environment} (including using \texttt{sys.frame} to access the currently active function calls). The \texttt{envir} argument is an alternative way to specify an environment, but is primarily there for back compatibility.

It is not allowed to remove variables from the base environment and base namespace, nor from any environment which is locked (see \texttt{lockEnvironment}).

Earlier versions of \texttt{R} incorrectly claimed that supplying a character vector in \texttt{...} removed the objects named in the character vector, but it removed the character vector. Use the \texttt{list} argument to specify objects \textit{via} a character vector.

References

See Also

\texttt{ls, objects}
Examples

tmp <- 1:4
## work with tmp and cleanup
rm(tmp)

## Not run:
## remove (almost) everything in the working environment.
## You will get no warning, so don’t do this unless you are really sure.
rm(list = ls())

## End(Not run)

rep Replicate Elements of Vectors and Lists

Description

rep replicates the values in x. It is a generic function, and the (internal) default method is described here.

rep.int and rep_len are faster simplified versions for two common cases. Internally, they are generic, so methods can be defined for them (see InternalMethods).

Usage

rep(x, ...)

rep.int(x, times)

rep_len(x, length.out)

Arguments

x a vector (of any mode including a list) or a factor or (for rep only) a POSIXct or POSIXlt or Date object; or an S4 object containing such an object.

... further arguments to be passed to or from other methods. For the internal default method these can include:

times an integer-valued vector giving the (non-negative) number of times to repeat each element if of length length(x), or to repeat the whole vector if of length 1. Negative or NA values are an error. A double vector is accepted, other inputs being coerced to an integer or double vector.

length.out non-negative integer. The desired length of the output vector. Other inputs will be coerced to a double vector and the first element taken. Ignored if NA or invalid.

each non-negative integer. Each element of x is repeated each times. Other inputs will be coerced to an integer or double vector and the first element taken. Treated as 1 if NA or invalid.

times, length.out see ... above.
Details

The default behaviour is as if the call was

\[
\text{rep}(x, \text{times }= 1, \text{length.out }= \text{NA}, \text{each }= 1)
\]

Normally just one of the additional arguments is specified, but if each is specified with either of the other two, its replication is performed first, and then that implied by times or length.out.

If times consists of a single integer, the result consists of the whole input repeated this many times. If times is a vector of the same length as x (after replication by each), the result consists of \(x[1]\) repeated times[1] times, \(x[2]\) repeated times[2] times and so on.

length.out may be given in place of times, in which case x is repeated as many times as is necessary to create a vector of this length. If both are given, length.out takes priority and times is ignored.

Non-integer values of times will be truncated towards zero. If times is a computed quantity it is prudent to add a small fuzz or use round. And analogously for each.

If x has length zero and length.out is supplied and is positive, the values are filled in using the extraction rules, that is by an NA of the appropriate class for an atomic vector (\(0\) for raw vectors) and NULL for a list.

Value

An object of the same type as x.

rep.int and rep_len return no attributes (except the class if returning a factor).

The default method of rep gives the result names (which will almost always contain duplicates) if x had names, but retains no other attributes.

Note

Function rep.int is a simple case which was provided as a separate function partly for S compatibility and partly for speed (especially when names can be dropped). The performance of rep has been improved since, but rep.int is still at least twice as fast when x has names.

The name rep.int long precedes making rep generic.

Function rep is a primitive, but (partial) matching of argument names is performed as for normal functions.

For historical reasons rep (only) works on NULL: the result is always NULL even when length.out is positive.

Although it has never been documented, these functions have always worked on expression vectors.

References

See Also

seq, sequence, replicate.
Examples

```r
rep(1:4, 2)
rep(1:4, each = 2)  # not the same.
rep(1:4, c(2,2,2,2))  # same as second.
rep(1:4, c(2,1,2,1))
rep(1:4, each = 2, len = 4)  # first 4 only.
rep(1:4, each = 2, len = 10)  # 8 integers plus two recycled 1's.
rep(1:4, each = 2, times = 3)  # length 24, 3 complete replications.
rep(1, 40*(1-.8))  # length 7 on most platforms.
rep(1, 40*(1-.8)+1e-7)  # better.

### replicate a list
fred <- list(happy = 1:10, name = "squash")
rep(fred, 5)

# date-time objects
x <- .leap.seconds[1:3]
rep(x, 2)
rep(as.POSIXlt(x), rep(2, 3))

### named factor
x <- factor(LETTERS[1:4]); names(x) <- letters[1:4]
x
rep(x, 2)
rep(x, each = 2)
rep.int(x, 2)  # no names
rep_len(x, 10)
```

---

**replace**

*Replace Values in a Vector*

**Description**

*replace* replaces the values in *x* with indices given in *list* by those given in *values*. If necessary, the values in *values* are recycled.

**Usage**

```r
replace(x, list, values)
```

**Arguments**

- `x` vector
- `list` an index vector
- `values` replacement values

**Value**

A vector with the values replaced.
Note

\( x \) is unchanged: remember to assign the result.

References

---

Reserved

Reserved Words in R

Description

The reserved words in R’s parser are

```r
if else repeat while function for in next break
TRUE FALSE NULL Inf NaN NA_integer_ NA_real_ NA_complex_ NA_character_
... and ..1, ..2 etc, which are used to refer to arguments passed down from a calling function, see ....
```

Details

Reserved words outside quotes are always parsed to be references to the objects linked to in the ‘Description’, and hence they are not allowed as syntactic names (see `make.names`). They are allowed as non-syntactic names, e.g. inside `backtick` quotes.

---

rev

Reverse Elements

Description

`rev` provides a reversed version of its argument. It is generic function with a default method for vectors and one for `dendrograms`.

Note that this is no longer needed (nor efficient) for obtaining vectors sorted into descending order, since that is now rather more directly achievable by `sort(x, decreasing = TRUE)`.

Usage

`rev(x)`

Arguments

\( x \) a vector or another object for which reversal is defined.

References

Rhome

Description
Return the R home directory, or the full path to a component of the R installation.

Usage
R.home(component = "home")

Arguments
component As well as "home" which gives the R home directory, other known values are "bin", "doc", "etc", "include", "modules" and "share" giving the paths to the corresponding parts of an R installation.

Details
The R home directory is the top-level directory of the R installation being run. The R home directory is often referred to as R_HOME, and is the value of an environment variable of that name in an R session. It can be found outside an R session by R RHOME.

Value
A character string giving the R home directory or path to a particular component. Normally the components are all subdirectories of the R home directory, but this need not be the case in a Unix-like installation.

The value for "modules" and on Windows "bin" is a sub-architecture-specific location. On a Unix-alike, the constructed paths are based on the current values of the environment variables R_HOME and where set R_SHARE_DIR, R_DOC_DIR and R_INCLUDE_DIR (these are set on startup and should not be altered).

On Windows the values of R.home() and R_HOME are switched to the 8.3 short form of path elements if required and if the Windows service to do that is enabled. The value of R_HOME is set to use forward slashes (since many package maintainers pass it unquoted to shells, for example in 'Makefile's).

See Also
commandArgs() [1] may provide related information.

Examples
```r
x <- c(1:5, 5:3)
## sort into descending order; first more efficiently:
stopifnot(sort(x, decreasing = TRUE) == rev(sort(x)))
stopifnot(rev(1:7) == 7:1)  # don't need 'rev' here
```
Examples

```r
## These result quite platform dependently:
rbind(home = R.home(),
       bin = R.home("bin")) # often a sub directory of 'home'
list.files(R.home("bin"))
```

Description

Compute the lengths and values of runs of equal values in a vector – or the reverse operation.

Usage

```r
rle(x)
inverse.rle(x, ...)
```

## S3 method for class 'rle'
```r
print(x, digits = getOption("digits"), prefix = "", ...)
```

Arguments

- `x`: a vector (atomic, not a list) for `rle()`; an object of class "rle" for `inverse.rle()`.
- `...`: further arguments; ignored here.
- `digits`: number of significant digits for printing, see `print.default`.
- `prefix`: character string, prepended to each printed line.

Details

'vector' is used in the sense of `is.vector`.

Missing values are regarded as unequal to the previous value, even if that is also missing.

`inverse.rle()` is the inverse function of `rle()`, reconstructing `x` from the runs.

Value

`rle()` returns an object of class "rle" which is a list with components:

- `lengths`: an integer vector containing the length of each run.
- `values`: a vector of the same length as `lengths` with the corresponding values.

`inverse.rle()` returns an atomic vector.
Examples

```r
x <- rev(rep(6:10, 1:5))
rle(x)
## lengths [1:5] 5 4 3 2 1
## values [1:5] 10 9 8 7 6
z <- c(TRUE, TRUE, FALSE, FALSE, TRUE, FALSE, TRUE, TRUE, TRUE)
rle(z)
rle(as.character(z))
print(rle(z), prefix = "..| ")
N <- integer(0)
stopifnot(x == inverse.rle(rle(x)),
           identical(N, inverse.rle(rle(N))),
           z == inverse.rle(rle(z)))
```

Round

### Rounding of Numbers

**Description**

- `ceiling` takes a single numeric argument `x` and returns a numeric vector containing the smallest integers not less than the corresponding elements of `x`.
- `floor` takes a single numeric argument `x` and returns a numeric vector containing the largest integers not greater than the corresponding elements of `x`.
- `trunc` takes a single numeric argument `x` and returns a numeric vector containing the integers formed by truncating the values in `x` toward 0.
- `round` rounds the values in its first argument to the specified number of decimal places (default 0). See ‘Details’ about “round to even” when rounding off a 5.
- `signif` rounds the values in its first argument to the specified number of significant digits.

**Usage**

- `ceiling(x)`
- `floor(x)`
- `trunc(x, ...)`
- `round(x, digits = 0)`
- `signif(x, digits = 6)`

**Arguments**

- `x` a numeric vector. Or, for `round` and `signif`, a complex vector.
- `digits` integer indicating the number of decimal places (`round`) or significant digits (`signif`) to be used. Negative values are allowed (see ‘Details’).
- `...` arguments to be passed to methods.
Details

These are generic functions: methods can be defined for them individually or via the \texttt{Math} group generic.

Note that for rounding off a 5, the IEC 60559 standard (see also ‘IEEE 754’) is expected to be used, ‘\textit{go to the even digit}’. Therefore \texttt{round(0.5)} is 0 and \texttt{round(-1.5)} is -2. However, this is dependent on OS services and on representation error (since e.g. 0.15 is not represented exactly, the rounding rule applies to the represented number and not to the printed number, and so \texttt{round(0.15,1)} could be either 0.1 or 0.2).

Rounding to a negative number of digits means rounding to a power of ten, so for example \texttt{round(x, digits = -2)} rounds to the nearest hundred.

For \texttt{signif} the recognized values of \texttt{digits} are 1...22, and non-missing values are rounded to the nearest integer in that range. Complex numbers are rounded to retain the specified number of digits in the larger of the components. Each element of the vector is rounded individually, unlike printing.

These are all primitive functions.

S4 methods

These are all (internally) S4 generic.

\texttt{ceiling}, \texttt{floor} and \texttt{trunc} are members of the \texttt{Math} group generic. As an S4 generic, \texttt{trunc} has only one argument.

\texttt{round} and \texttt{signif} are members of the \texttt{Math2} group generic.

Warning

The realities of computer arithmetic can cause unexpected results, especially with \texttt{floor} and \texttt{ceiling}. For example, we ‘know’ that \texttt{floor(log(x,base = 8))} for \(x = 8\) is 1, but 0 has been seen on an R platform. It is normally necessary to use a tolerance.

Rounding to decimal digits in binary arithmetic is non-trivial (when \texttt{digits} != 0) and may be surprising. Be aware that most decimal fractions are not exactly representable in binary double precision. In R 4.0.0, the algorithm for \texttt{round(x, d)}, for \(d > 0\), has been improved to \texttt{measure} and round ‘to nearest even’, contrary to earlier versions of R (or also to \texttt{sprintf()} or \texttt{format()} based rounding).

References

The ISO/IEC/IEEE 60559:2011 standard is available for money from \url{https://www.iso.org}.

The IEEE 754:2008 standard is more openly documented, e.g. at \url{https://en.wikipedia.org/wiki/IEEE_754}.

See Also

\texttt{as.integer}. Package \texttt{round}’s \texttt{roundX()} for several versions or implementations of rounding, including some previous and the current R version (as \texttt{version = "3d.C"}).
Examples

```r
round(.5 + -2:4) # IEEE / IEC rounding: -2 0 0 2 2 4 4
## (this is *good* behaviour -- do *NOT* report it as bug !)

(x1 <- seq(-2, 4, by = .5))
round(x1) ##-- IEEE / IEC rounding !
x1[trunc(x1) != floor(x1)]

non.int <- ceiling(x1) != floor(x1)

x2 <- pi * 100^(-1:3)
round(x2, 3)
signif(x2, 3)
```

---

**round.POSIXt**

**Round / Truncate Data-Time Objects**

**Description**

Round or truncate date-time objects.

**Usage**

```r
## S3 method for class 'POSIXt'
round(x,
    units = c("secs", "mins", "hours", "days", "months", "years"))

## S3 method for class 'POSIXt'
trunc(x,
    units = c("secs", "mins", "hours", "days", "months", "years"),
    ...)

## S3 method for class 'Date'
round(x, ...)

## S3 method for class 'Date'
trunc(x, ...)
```

**Arguments**

- `x`: an object inheriting from "POSIXt" or "Date".
- `units`: one of the units listed. Can be abbreviated.
- `...`: arguments to be passed to or from other methods, notably digits for `round`.

**Details**

The time is rounded or truncated to the second, minute, hour, day, month or year. Time zones are only relevant to days or more, when midnight in the current time zone is used.

The methods for class "Date" are of little use except to remove fractional days.

**Value**

An object of class "POSIXlt" or "Date".
See Also

\textit{round} for the generic function and default methods.
\textit{DateTimeClasses, Date}

Examples

\begin{verbatim}
round(.leap.seconds + 1000, "hour")
trunc(Sys.time(), "day")
\end{verbatim}

\begin{tabular}{ll}
\textbf{row} & \textit{Row Indexes} \\
\hline
\end{tabular}

Description

Returns a matrix of integers indicating their row number in a matrix-like object, or a factor indicating the row labels.

Usage

\begin{verbatim}
row(x, as.factor = FALSE)
.row(dim)
\end{verbatim}

Arguments

- \textbf{x} a matrix-like object, that is one with a two-dimensional \texttt{dim}.
- \textbf{dim} a matrix dimension, i.e., an integer valued numeric vector of length two (with non-negative entries).
- \textbf{as.factor} a logical value indicating whether the value should be returned as a factor of row labels (created if necessary) rather than as numbers.

Value

An integer (or factor) matrix with the same dimensions as \texttt{x} and whose $ij$-th element is equal to $i$ (or the $i$-th row label).

References

See Also

\textit{col} to get columns; \textit{slice.index} for a general way to get slice indices in an array.
Examples

x <- matrix(1:12, 3, 4)
# extract the diagonal of a matrix - more slowly than diag(x)
dx <- x[row(x) == col(x)]
dx

# create an identity 5-by-5 matrix more slowly than diag(n = 5):
x <- matrix(0, nrow = 5, ncol = 5)
x[row(x) == col(x)] <- 1
x

(i34 <- .row(3:4))
stopifnot(identical(i34, .row(c(3,4)))) # 'dim' maybe "double"

---

row+colnames  

Row and Column Names

Description

Retrieve or set the row or column names of a matrix-like object.

Usage

rownames(x, do.NULL = TRUE, prefix = "row")
rownames(x) <- value

colnames(x, do.NULL = TRUE, prefix = "col")
colnames(x) <- value

Arguments

x  
a matrix-like R object, with at least two dimensions for colnames.
do.NULL  
logical. If FALSE and names are NULL, names are created.
prefix  
for created names.
value  
a valid value for that component of dimnames(x). For a matrix or array this is either NULL or a character vector of non-zero length equal to the appropriate dimension.

Details

The extractor functions try to do something sensible for any matrix-like object x. If the object has dimnames the first component is used as the row names, and the second component (if any) is used for the column names. For a data frame, rownames and colnames eventually call row.names and names respectively, but the latter are preferred.

If do.NULL is FALSE, a character vector (of length NROW(x) or NCOL(x)) is returned in any case, prepending prefix to simple numbers, if there are no dimnames or the corresponding component of the dimnames is NULL.

The replacement methods for arrays/matrices coerce vector and factor values of value to character, but do not dispatch methods for as.character.
For a data frame, value for rownames should be a character vector of non-duplicated and non-missing names (this is enforced), and for colnames a character vector of (preferably) unique syntactically-valid names. In both cases, value will be coerced by `as.character`, and setting colnames will convert the row names to character.

**Note**

If the replacement versions are called on a matrix without any existing dimnames, they will add suitable dimnames. But constructions such as

`rownames(x)[3] <- "c"`

may not work unless x already has dimnames, since this will create a length-3 value from the NULL value of `rownames(x)`.

**See Also**

`dimnames, case.names, variable.names`.

**Examples**

```r
m0 <- matrix(NA, 4, 0)
rownames(m0)

m2 <- cbind(1, 1:4)
colnames(m2) <- c("x","y")
rownames(m2) <- rownames(m2, do.NULL = FALSE, prefix = "Obs.")
m2
```

---

**Description**

All data frames have row names, a character vector of length the number of rows with no duplicates nor missing values.

There are generic functions for getting and setting row names, with default methods for arrays. The description here is for the `data.frame` method.

`.rowNamesDF<-` is a (non-generic replacement) function to set row names for data frames, with extra argument `make.names`. This function only exists as workaround as we cannot easily change the `rownames<-` generic without breaking legacy code in existing packages.

**Usage**

```r
rownames(x)
rownames(x) <- value
.rowNamesDF(x, make.names=FALSE) <- value
```
Arguments

x: object of class "data.frame", or any other class for which a method has been defined.

make.names: logical, i.e., one of FALSE, NA, TRUE, indicating what should happen if the specified row names, i.e., `value`, are invalid, e.g., duplicated or NA. The default (is back compatible), FALSE, will signal an error, where NA will "automatic" row names and TRUE will call `make.names(value, unique=TRUE)` for constructing valid names.

value: an object to be coerced to character unless an integer vector. It should have (after coercion) the same length as the number of rows of `x` with no duplicated nor missing values. NULL is also allowed: see 'Details'.

Details

A data frame has (by definition) a vector of row names which has length the number of rows in the data frame, and contains neither missing nor duplicated values. Where a row names sequence has been added by the software to meet this requirement, they are regarded as 'automatic'.

Row names are currently allowed to be integer or character, but for backwards compatibility (with R <= 2.4.0) `row.names` will always return a character vector. (Use `attr(x,"row.names")` if you need to retrieve an integer-valued set of row names.)

Using NULL for the value resets the row names to `seq_len(nrow(x))`, regarded as 'automatic'.

Value

`row.names` returns a character vector.

`row.names<-` returns a data frame with the row names changed.

Note

`row.names` is similar to `rownames` for arrays, and it has a method that calls `rownames` for an array argument.

Row names of the form `1:n` for `n > 2` are stored internally in a compact form, which might be seen from C code or by deparsing but never via `row.names` or `attr(x,"row.names")`. Additionally, some names of this sort are marked as 'automatic' and handled differently by `as.matrix` and `data.matrix` (and potentially other functions). (All zero-row data frames are regarded as having automatic row names.)

References

See Also

data.frame, rownames, names.
.row_names_info for the internal representations.
Examples

```r
## To illustrate the note:
df <- data.frame(x = c(TRUE, FALSE, NA, NA), y = c(12, 34, 56, 78))
row.names(df) <- 1:4
attr(df, "row.names")
deparse(df)
## (Compact storage, not regarded as automatic.)
row.names(df) <- NULL
attr(df, "row.names")
deparse(df)
## (Compact storage, regarded as automatic.)
```

Description

Compute column sums across rows of a numeric matrix-like object for each level of a grouping variable. rowsum is generic, with a method for data frames and a default method for vectors and matrices.

Usage

```r
rowsum(x, group, reorder = TRUE, ...)  
## S3 method for class 'data.frame'  
rowsum(x, group, reorder = TRUE, na.rm = FALSE, ...)  
## Default S3 method:  
rowsum(x, group, reorder = TRUE, na.rm = FALSE, ...)
```

Arguments

- **x**: a matrix, data frame or vector of numeric data. Missing values are allowed. A numeric vector will be treated as a column vector.
- **group**: a vector or factor giving the grouping, with one element per row of x. Missing values will be treated as another group and a warning will be given.
- **reorder**: if TRUE, then the result will be in order of `sort(unique(group))`, if FALSE, it will be in the order that groups were encountered.
- **na.rm**: logical (TRUE or FALSE). Should NA (including NaN) values be discarded?
- **...**: other arguments to be passed to or from methods

Details

The default is to reorder the rows to agree with `tapply` as in the example below. Reordering should not add noticeably to the time except when there are very many distinct values of group and x has few columns.

The original function was written by Terry Therneau, but this is a new implementation using hashing that is much faster for large matrices.

To sum over all the rows of a matrix (i.e., a single group) use `colSums`, which should be even faster.

For integer arguments, over/underflow in forming the sum results in NA.
Value

A matrix or data frame containing the sums. There will be one row per unique value of group.

See Also

tapply, aggregate, rowSums

Examples

```r
require(stats)
x <- matrix(runif(100), ncol = 5)
group <- sample(1:8, 20, TRUE)
(xsum <- rowsum(x, group))
## Slower versions
tapply(x, list(group[row(x)], col(x)), sum)
t(sapply(split(as.data.frame(x), group), colSums))
aggregate(x, list(group), sum)[-1]
```

S3method

Register S3 Methods

Description

Register S3 methods in R scripts.

Usage

`.S3method(generic, class, method)`

Arguments

generic
  a character string naming an S3 generic function.

class
  a character string naming an S3 class.

method
  a character string or function giving the S3 method to be registered. If not given, the function named `generic.class` is used.

Details

This function should only be used in R scripts: for package code, one should use the corresponding ‘S3method’ ‘NAMESPACE’ directive.

Examples

```r
## Create a generic function and register a method for objects
## inheriting from class 'cls':
gen <- function(x) UseMethod("gen")
met <- function(x) writeLines("Hello world.")
.S3method("gen", "cls", met)
## Create an object inheriting from class 'cls', and call the
## generic on it:
x <- structure(123, class = "cls")
gen(x)
```
sample

Random Samples and Permutations

Description

sample takes a sample of the specified size from the elements of x using either with or without replacement.

Usage

sample(x, size, replace = FALSE, prob = NULL)

sample.int(n, size = n, replace = FALSE, prob = NULL,
    useHash = (!replace && is.null(prob) && size <= n/2 && n > 1e7))

Arguments

x 
either a vector of one or more elements from which to choose, or a positive integer. See ‘Details.’

n 
a positive number, the number of items to choose from. See ‘Details.’

size 
a non-negative integer giving the number of items to choose.

replace 
should sampling be with replacement?

prob 
a vector of probability weights for obtaining the elements of the vector being sampled.

useHash 
logical indicating if the hash-version of the algorithm should be used. Can only be used for replace = FALSE, prob = NULL, and size <= n/2, and really should be used for large n, as useHash=FALSE will use memory proportional to n.

Details

If x has length 1, is numeric (in the sense of is.numeric) and x >= 1, sampling via sample takes place from 1:x. Note that this convenience feature may lead to undesired behaviour when x is of varying length in calls such as sample(x). See the examples.

Otherwise x can be any R object for which length and subsetting by integers make sense: S3 or S4 methods for these operations will be dispatched as appropriate.

For sample the default for size is the number of items inferred from the first argument, so that sample(x) generates a random permutation of the elements of x (or 1:x).

It is allowed to ask for size = 0 samples with n = 0 or a length-zero x, but otherwise n > 0 or positive length(x) is required.

Non-integer positive numerical values of n or x will be truncated to the next smallest integer, which has to be no larger than .Machine$integer.max.

The optional prob argument can be used to give a vector of weights for obtaining the elements of the vector being sampled. They need not sum to one, but they should be non-negative and not all zero. If replace is true, Walker’s alias method (Ripley, 1987) is used when there are more than 200 reasonably probable values: this gives results incompatible with those from R < 2.2.0.
If replace is false, these probabilities are applied sequentially, that is the probability of choosing the next item is proportional to the weights amongst the remaining items. The number of nonzero weights must be at least size in this case.

sample.int is a bare interface in which both n and size must be supplied as integers.

Argument n can be larger than the largest integer of type integer, up to the largest representable integer in type double. Only uniform sampling is supported. Two random numbers are used to ensure uniform sampling of large integers.

**Value**

For `sample` a vector of length size with elements drawn from either `x` or from the integers `1:x`.

For `sample.int`, an integer vector of length size with elements from `1:n`, or a double vector if \( n \geq 2^{31} \).

**References**

**See Also**

`RNGkind(sample.kind = ..)` about random number generation, notably the change of `sample()` results with R version 3.6.0.

CRAN package `sampling` for other methods of weighted sampling without replacement.

**Examples**

```r
x <- 1:12
# a random permutation
sample(x)
# bootstrap resampling -- only if length(x) > 1 !
sample(x, replace = TRUE)

# 100 Bernoulli trials
sample(c(0,1), 100, replace = TRUE)

## More careful bootstrapping -- Consider this when using sample()
## programmatically (i.e., in your function or simulation)!

# sample()’s surprise -- example
x <- 1:10
sample(x[x > 8]) # length 2
sample(x[x > 9]) # oops -- length 10!
sample(x[x > 10]) # length 0

## safer version:
resample <- function(x, ...) x[sample.int(length(x), ...)]
resample(x[x > 8]) # length 2
resample(x[x > 9]) # length 1
resample(x[x > 10]) # length 0

## R 3.x.y only
sample.int(1e10, 12, replace = TRUE)
```
sample.int(1e10, 12) # not that there is much chance of duplicates

---

**save**

**Save R Objects**

**Description**

`save` writes an external representation of R objects to the specified file. The objects can be read back from the file at a later date by using the function `load` or `attach` (or `data` in some cases).

`save.image()` is just a short-cut for 'save my current workspace', i.e., `save(list = ls(all.names = TRUE), file = "RData", envir = .GlobalEnv)`. It is also what happens with `q("yes")`.

**Usage**

```r
save(..., list = character(),
     file = stop("'file' must be specified"),
     ascii = FALSE, version = NULL, envir = parent.frame(),
     compress = isTRUE(!ascii), compression_level,
     eval.promises = TRUE, precheck = TRUE)

save.image(file = ".RData", version = NULL, ascii = FALSE,
            compress = !ascii, safe = TRUE)
```

**Arguments**

- `...`: the names of the objects to be saved (as symbols or character strings).
- `list`: A character vector containing the names of objects to be saved.
- `file`: a (writable binary-mode) connection or the name of the file where the data will be saved (when tilde expansion is done). Must be a file name for `save.image` or version = 1.
- `ascii`: if TRUE, an ASCII representation of the data is written. The default value of `ascii` is FALSE which leads to a binary file being written. If NA and version >= 2, a different ASCII representation is used which writes double/complex numbers as binary fractions.
- `version`: the workspace format version to use. NULL specifies the current default format (3). Version 1 was the default from R 0.99.0 to R 1.3.1 and version 2 from R 1.4.0 to 3.5.0. Version 3 is supported from R 3.5.0.
- `envir`: environment to search for objects to be saved.
- `compress`: logical or character string specifying whether saving to a named file is to use compression. TRUE corresponds to gzip compression, and character strings "gzip", "bzip2" or "xz" specify the type of compression. Ignored when file is a connection and for workspace format version 1.
- `compression_level`: integer: the level of compression to be used. Defaults to 6 for gzip compression and to 9 for bzip2 or xz compression. See the help for `file` for possible values and their merits.
- `eval.promises`: logical: should objects which are promises be forced before saving?
precheck logical: should the existence of the objects be checked before starting to save (and in particular before opening the file/connection)? Does not apply to version 1 saves.

safe logical. If TRUE, a temporary file is used for creating the saved workspace. The temporary file is renamed to file if the save succeeds. This preserves an existing workspace file if the save fails, but at the cost of using extra disk space during the save.

Details

The names of the objects specified either as symbols (or character strings) in ... or as a character vector in list are used to look up the objects from environment envir. By default promises are evaluated, but if eval.promises = FALSE promises are saved (together with their evaluation environments). (Promises embedded in objects are always saved unevaluated.)

All R platforms use the XDR (bigendian) representation of C ints and doubles in binary save-d files, and these are portable across all R platforms.

ASCII saves used to be useful for moving data between platforms but are now mainly of historical interest. They can be more compact than binary saves where compression is not used, but are almost always slower to both read and write: binary saves compress much better than ASCII ones. Further, decimal ASCII saves may not restore double/complex values exactly, and what value is restored may depend on the R platform.

Default values for the ascii, compress, safe and version arguments can be modified with the "save.defaults" option (used both by save and save.image), see also the 'Examples' section. If a "save.image.defaults" option is set it is used in preference to "save.defaults" for function save.image (which allows this to have different defaults). In addition, compression_level can be part of the "save.defaults" option.

A connection that is not already open will be opened in mode "wb". Supplying a connection which is open and not in binary mode gives an error.

Compression

Large files can be reduced considerably in size by compression. A particular 46MB R object was saved as 35MB without compression in 2 seconds, 22MB with gzip compression in 8 secs, 19MB with bzip2 compression in 13 secs and 9.4MB with xz compression in 40 secs. The load times were 1.3, 2.8, 5.5 and 5.7 seconds respectively. These results are indicative, but the relative performances do depend on the actual file: xz compressed unusually well here.

It is possible to compress later (with gzip, bzip2 or xz) a file saved with compress = FALSE: the effect is the same as saving with compression. Also, a saved file can be uncompressed and recompressed under a different compression scheme (and see resaveRdaFiles for a way to do so from within R).

Parallel compression

That file can be a connection can be exploited to make use of an external parallel compression utility such as pigz (https://zlib.net/pigz/) or pbzip2 (https://launchpad.net/pbzip2) via a pipe connection. For example, using 8 threads,

```r
con <- pipe("pigz -p8 > fname.gz", "wb")
save(myObj, file = con); close(con)
con <- pipe("pbzip2 -p8 -9 > fname.bz2", "wb")
```
save(myObj, file = con); close(con)

con <- pipe("xz -T8 -6 -e > fname.xz", "wb")
save(myObj, file = con); close(con)

where the last requires xz 5.1.1 or later built with support for multiple threads (and parallel compression is only effective for large objects: at level 6 it will compress in serialized chunks of 12MB).

**Warnings**

The ... arguments only give the names of the objects to be saved: they are searched for in the environment given by the envir argument, and the actual objects given as arguments need not be those found.

Saved R objects are binary files, even those saved with ascii = TRUE, so ensure that they are transferred without conversion of end-of-line markers and of 8-bit characters. The lines are delimited by LF on all platforms.

Although the default version was not changed between R 1.4.0 and R 3.4.4 nor since R 3.5.0, this does not mean that saved files are necessarily backwards compatible. You will be able to load a saved image into an earlier version of R which supports its version unless use is made of later additions (for example for version 2, raw vectors, external pointers and some S4 objects).

One such 'later addition' was long vectors, introduced in R 3.0.0 and loadable only on 64-bit platforms.

Loading files saved with ASCII = NA requires a C99-compliant C function sscanf: this is a problem on Windows, first worked around in R 3.1.2: version-2 files in that format should be readable in earlier versions of R on all other platforms.

**Note**

For saving single R objects, saveRDS() is mostly preferable to save(), notably because of the functional nature of readRDS(), as opposed to load().

The most common reason for failure is lack of write permission in the current directory. For save.image and for saving at the end of a session this will shown by messages like

```
Error in gzfile(file, "wb") : unable to open connection
In addition: Warning message:
  In gzfile(file, "wb") :
    cannot open compressed file ".RDataTmp",
    probable reason 'Permission denied'
```

**See Also**

dput, dump, load, data.

For other interfaces to the underlying serialization format, see serialize and saveRDS.

**Examples**

```r
x <- stats::runif(20)
y <- list(a = 1, b = TRUE, c = "oops")
save(x, y, file = "xy.RData")
save.image() # creating ".RData" in current working directory
unlink("xy.RData")
```
scale

Scaling and Centering of Matrix-like Objects

Description

scale is generic function whose default method centers and/or scales the columns of a numeric matrix.

Usage

scale(x, center = TRUE, scale = TRUE)

Arguments

x
a numeric matrix(like object).

center
either a logical value or numeric-alike vector of length equal to the number of columns of x, where ‘numeric-alike’ means that as.numeric(.) will be applied successfully if is.numeric(.) is not true.

scale
either a logical value or a numeric-alike vector of length equal to the number of columns of x.

Details

The value of center determines how column centering is performed. If center is a numeric-alike vector with length equal to the number of columns of x, then each column of x has the corresponding value from center subtracted from it. If center is TRUE then centering is done by subtracting the column means (omitting NAs) of x from their corresponding columns, and if center is FALSE, no centering is done.

The value of scale determines how column scaling is performed (after centering). If scale is a numeric-alike vector with length equal to the number of columns of x, then each column of x is divided by the corresponding value from scale. If scale is TRUE then scaling is done by dividing the (centered) columns of x by their standard deviations if center is TRUE, and the root mean square otherwise. If scale is FALSE, no scaling is done.

The root-mean-square for a (possibly centered) column is defined as $\sqrt{\frac{\sum(x^2)}{n-1}}$, where $x$ is a vector of the non-missing values and $n$ is the number of non-missing values. In the case center = TRUE, this is the same as the standard deviation, but in general it is not. (To scale by the standard deviations without centering, use scale(x, center = FALSE, scale = apply(x, 2, sd, na.rm = TRUE)).)
Value

For `scale.default`, the centered, scaled matrix. The numeric centering and scalings used (if any) are returned as attributes "scaled:center" and "scaled:scale"

References

See Also

`sweep` which allows centering (and scaling) with arbitrary statistics.

For working with the scale of a plot, see `par`.

Examples

```r
require(stats)
x <- matrix(1:10, ncol = 2)
(centered.x <- scale(x, scale = FALSE))
cov(centered.scaled.x <- scale(x)) # all 1
```

Description

Read data into a vector or list from the console or file.

Usage

```r
scan(file = "", what = double(), nmax = -1, n = -1, sep = "", quote = if(identical(sep, "\n")) "" else "\"", dec = ".", skip = 0, nlines = 0, na.strings = "NA", flush = FALSE, fill = FALSE, strip.white = FALSE, quiet = FALSE, blank.lines.skip = TRUE, multi.line = TRUE, comment.char = "", allowEscapes = FALSE, fileEncoding = "", encoding = "unknown", text, skipNul = FALSE)
```

Arguments

- `file`: the name of a file to read data values from. If the specified file is "", then input is taken from the keyboard (or whatever `stdin()` reads if input is redirected or R is embedded). (In this case input can be terminated by a blank line or an EOF signal, 'Ctrl-D' on Unix and 'Ctrl-Z' on Windows.) Otherwise, the file name is interpreted relative to the current working directory (given by `getwd()`), unless it specifies an absolute path. Tilde-expansion is performed where supported. When running R from a script, `file = "stdin"` can be used to refer to the process’s stdin file stream. This can be a compressed file (see `file`). Alternatively, file can be a connection, which will be opened if necessary, and if so closed at the end of the function call. Whatever mode the connection
is opened in, any of LF, CRLF or CR will be accepted as the EOL marker for a line and so will match sep = "\n".

file can also be a complete URL. (For the supported URL schemes, see the ‘URLs’ section of the help for url.)

To read a data file not in the current encoding (for example a Latin-1 file in a UTF-8 locale or conversely) use a file connection setting its encoding argument (or scan’s fileEncoding argument).

what the type of what gives the type of data to be read. (Here ‘type’ is used in the sense of typeof.) The supported types are logical, integer, numeric, complex, character, raw and list. If what is a list, it is assumed that the lines of the data file are records each containing length(what) items (‘fields’) and the list components should have elements which are one of the first six (atomic) types listed or NULL, see section ‘Details’ below.

nmax the maximum number of data values to be read, or if what is a list, the maximum number of records to be read. If omitted or not positive or an invalid value for an integer (and nlines is not set to a positive value), scan will read to the end of file.

n integer: the maximum number of data values to be read, defaulting to no limit. Invalid values will be ignored.

sep by default, scan expects to read ‘white-space’ delimited input fields. Alternatively, sep can be used to specify a character which delimits fields. A field is always delimited by an end-of-line marker unless it is quoted. If specified this should be the empty character string (the default) or NULL or a character string containing just one single-byte character.

quote the set of quoting characters as a single character string or NULL. In a multibyte locale the quoting characters must be ASCII (single-byte).

dec decimal point character. This should be a character string containing just one single-byte character. (NULL and a zero-length character vector are also accepted, and taken as the default.)

skip the number of lines of the input file to skip before beginning to read data values.

nlines if positive, the maximum number of lines of data to be read.

na.strings character vector. Elements of this vector are to be interpreted as missing (NA) values. Blank fields are also considered to be missing values in logical, integer, numeric and complex fields. Note that the test happens after white space is stripped from the input, so na.strings values may need their own white space stripped in advance.

flush logical: if TRUE, scan will flush to the end of the line after reading the last of the fields requested. This allows putting comments after the last field, but precludes putting more that one record on a line.

fill logical: if TRUE, scan will implicitly add empty fields to any lines with fewer fields than implied by what.

strip.white vector of logical value(s) corresponding to items in the what argument. It is used only when sep has been specified, and allows the stripping of leading and trailing ‘white space’ from character fields (numeric fields are always stripped). Note: white space inside quoted strings is not stripped.

If strip.white is of length 1, it applies to all fields; otherwise, if strip.white[i] is TRUE and the i-th field is of mode character (because what[i] is) then the leading and trailing unquoted white space from field i is stripped.
quiet logical: if FALSE (default), scan() will print a line, saying how many items have been read.

blank.lines.skip logical: if TRUE blank lines in the input are ignored, except when counting skip and nlines.

multi.line logical. Only used if what is a list. If FALSE, all of a record must appear on one line (but more than one record can appear on a single line). Note that using fill = TRUE implies that a record will be terminated at the end of a line.

comment.char character: a character vector of length one containing a single character or an empty string. Use "" to turn off the interpretation of comments altogether (the default).

allowEscapes logical. Should C-style escapes such as ‘\n’ be processed (the default) or read verbatim? Note that if not within quotes these could be interpreted as a delimiter (but not as a comment character).

The escapes which are interpreted are the control characters ‘\a’, ‘\b’, ‘\f’, ‘\n’, ‘\r’, ‘\t’, ‘\v’ and octal and hexadecimal representations like ‘\040’ and ‘\0x2A’. Any other escaped character is treated as itself, including backslash. Note that Unicode escapes (starting ‘\u’ or ‘\U’: see Quotes) are never processed.

fileEncoding character string: if non-empty declares the encoding used on a file (not a connection nor the keyboard) so the character data can be re-encoded. See the ‘Encoding’ section of the help for file, and the ‘R Data Import/Export Manual’.

encoding encoding to be assumed for input strings. If the value is “latin1” or “UTF-8” it is used to mark character strings as known to be in Latin-1 or UTF-8: it is not used to re-encode the input (see fileEncoding). See also ‘Details’.

text character string: if file is not supplied and this is, then data are read from the value of text via a text connection.

skipNul logical: should nuls be skipped when reading character fields?

Details

The value of what can be a list of types, in which case scan returns a list of vectors with the types given by the types of the elements in what. This provides a way of reading columnar data. If any of the types is NULL, the corresponding field is skipped (but a NULL component appears in the result).

The type of what or its components can be one of the six atomic vector types or NULL (see is.atomic).

‘White space’ is defined for the purposes of this function as one or more contiguous characters from the set space, horizontal tab, carriage return and line feed. It does not include form feed nor vertical tab, but in Latin-1 and Windows 8-bit locales (but not UTF-8) ‘space’ includes the non-breaking space ‘\xa0’.

Empty numeric fields are always regarded as missing values. Empty character fields are scanned as empty character vectors, unless na.strings contains "" when they are regarded as missing values.

The allowed input for a numeric field is optional whitespace followed either NA or an optional sign followed by a decimal or hexadecimal constant (see NumericConstants), or NaN, Inf or infinity (ignoring case). Out-of-range values are recorded as Inf, -Inf or 0.

For an integer field the allowed input is optional whitespace, followed by either NA or an optional sign and one or more digits (‘0’–‘9’): all out-of-range values are converted to NA_integer_.

If sep is the default ‘”‘, the character ‘\’ in a quoted string escapes the following character, so quotes may be included in the string by escaping them.
If `sep` is non-default, the fields may be quoted in the style of `.csv` files where separators inside quotes (', ' or "") are ignored and quotes may be put inside strings by doubling them. However, if `sep = "\n"` it is assumed by default that one wants to read entire lines verbatim.

Quoting is only interpreted in character fields and in `NULL` fields (which might be skipping character fields).

Note that since `sep` is a separator and not a terminator, reading a file by `scan("foo",sep = "\n",blank.lines.skip = FALSE)` will give an empty final line if the file ends in a linefeed and not if it does not. This might not be what you expected; see also `readLines`.

If `comment.char` occurs (except inside a quoted character field), it signals that the rest of the line should be regarded as a comment and be discarded. Lines beginning with a comment character (possibly after white space with the default separator) are treated as blank lines.

There is a line-length limit of 4095 bytes when reading from the console (which may impose a lower limit: see ‘An Introduction to R’).

There is a check for a user interrupt every 1000 lines if `what` is a list, otherwise every 10000 items.

If `file` is a character string and `fileEncoding` is non-default, or if it is a not-already-open connection with a non-default `encoding` argument, the text is converted to UTF-8 and declared as such (and the encoding argument to `scan` is ignored). See the examples of `readLines`.

Embedded nuls in the input stream will terminate the field currently being read, with a warning once per call to `scan`. Setting `skipNul = TRUE` causes them to be ignored.

**Value**

if `what` is a list, a list of the same length and same names (as any) as `what`.

Otherwise, a vector of the type of `what`.

Character strings in the result will have a declared encoding if `encoding` is "latin1" or "UTF-8".

**Note**

The default for `multi.line` differs from S. To read one record per line, use `flush = TRUE` and `multi.line = FALSE`. (Note that quoted character strings can still include embedded newlines.)

If number of items is not specified, the internal mechanism re-allocates memory in powers of two and so could use up to three times as much memory as needed. (It needs both old and new copies.)

If you can, specify either `n` or `nmax` whenever inputting a large vector, and `nmax` or `nlines` when inputting a large list.

Using `scan` on an open connection to read partial lines can lose chars: use an explicit separator to avoid this.

Having nul bytes in fields (including ‘\0’ if `allowEscapes = TRUE`) may lead to interpretation of the field being terminated at the nul. They not normally present in text files – see `readBin`.

**References**

**See Also**

`read.table` for more user-friendly reading of data matrices; `readLines` to read a file a line at a time. `write`.

Quotes for the details of C-style escape sequences.
readChar and readBin to read fixed or variable length character strings or binary representations of numbers a few at a time from a connection.

Examples

cat("TITLE extra line", "2 3 5 7", "11 13 17", file = "ex.data", sep = "\n")
pp <- scan("ex.data", skip = 1, quiet = TRUE)
scan("ex.data", skip = 1)
scan("ex.data", skip = 1, nlines = 1) # only 1 line after the skipped one
scan("ex.data", what = list("" ", ", ")) # flush is F -> read "7"
scan("ex.data", what = list("" ", ", "), flush = TRUE)
unlink("ex.data") # tidy up

## "inline" usage
scan(text = "1 2 3")

search  
Give Search Path for R Objects

Description

Gives a list of attached packages (see library), and R objects, usually data.frames.

Usage

search()
searchpaths()

Value

A character vector, starting with ".GlobalEnv", and ending with "package:base" which is R's 
base package required always.

searchpaths gives a similar character vector, with the entries for packages being the path to the 
package used to load the code.

References

Brooks/Cole. (search.)

(searchpaths.)

See Also

.packages to list just the packages on search path.
.loadedNamespaces to list loaded namespaces.
attach and detach to change the search path, objects to find R objects in there.

Examples

search()
searchpaths()
Functions to Reposition Connections

Description
Functions to re-position connections.

Usage
seek(con, ...)
## S3 method for class 'connection'
seek(con, where = NA, origin = "start", rw = "", ...)

isSeekable(con)
truncates(con, ...)

Arguments
con a connection.
where numeric. A file position (relative to the origin specified by origin), or NA.
rw character string. Empty or "read" or "write", partial matches allowed.
origin character string. One of "start", "current", "end": see ‘Details’.
... further arguments passed to or from other methods.

Details
seek with where = NA returns the current byte offset of a connection (from the beginning), and with a non-missing where argument the connection is re-positioned (if possible) to the specified position. isSeekable returns whether the connection in principle supports seek: currently only (possibly gz-compressed) file connections do.

where is stored as a real but should represent an integer: non-integer values are likely to be truncated. Note that the possible values can exceed the largest representable number in an R integer on 64-bit builds, and on some 32-bit builds.

File connections can be open for both writing/appending, in which case R keeps separate positions for reading and writing. Which seek refers to can be set by its rw argument: the default is the last mode (reading or writing) which was used. Most files are only opened for reading or writing and so default to that state. If a file is open for both reading and writing but has not been used, the default is to give the reading position (0).

The initial file position for reading is always at the beginning. The initial position for writing is at the beginning of the file for modes "r+" and "r+b", otherwise at the end of the file. Some platforms only allow writing at the end of the file in the append modes. (The reported write position for a file opened in an append mode will typically be unreliable until the file has been written to.)

gzf file connections support seek with a number of limitations, using the file position of the uncompressed file. They do not support origin = "end". When writing, seeking is only possible forwards: when reading seeking backwards is supported by rewinding the file and re-reading from its start.

If seek is called with a non-NA value of where, any pushback on a text-mode connection is discarded.
truncate truncates a file opened for writing at its current position. It works only for file connections, and is not implemented on all platforms: on others (including Windows) it will not work for large (> 2Gb) files.

None of these should be expected to work on text-mode connections with re-encoding selected.

Value

seek returns the current position (before any move), as a (numeric) byte offset from the origin, if relevant, or 0 if not. Note that the position can exceed the largest representable number in an R integer on 64-bit builds, and on some 32-bit builds.

truncate returns NULL; it stops with an error if it fails (or is not implemented).

isSeekable returns a logical value, whether the connection supports seek.

Warning

Use of seek on Windows is discouraged. We have found so many errors in the Windows implementation of file positioning that users are advised to use it only at their own risk, and asked not to waste the R developers’ time with bug reports on Windows’ deficiencies.

connections

seq

Sequence Generation

Description

Generate regular sequences. seq is a standard generic with a default method. seq.int is a primitive which can be much faster but has a few restrictions. seq_along and seq_len are very fast primitives for two common cases.

Usage

seq(...)

## Default S3 method:
seq(from = 1, to = 1, by = ((to - from)/(length.out - 1)),
    length.out = NULL, along.with = NULL, ...)

seq.int(from, to, by, length.out, along.with, ...)

seq_along(along.with)
seq_len(length.out)
Arguments

... arguments passed to or from methods.

from, to the starting and (maximal) end values of the sequence. Of length 1 unless just from is supplied as an unnamed argument.

by number: increment of the sequence.

length.out desired length of the sequence. A non-negative number, which for seq and seq.int will be rounded up if fractional.

along.with take the length from the length of this argument.

details

Numerical inputs should all be finite (that is, not infinite, NaN or NA).

The interpretation of the unnamed arguments of seq and seq.int is not standard, and it is recommended always to name the arguments when programming.

seq is generic, and only the default method is described here. Note that it dispatches on the class of the first argument irrespective of argument names. This can have unintended consequences if it is called with just one argument intending this to be taken as along.with: it is much better to use seq_along in that case.

seq.int is an internal generic which dispatches on methods for "seq" based on the class of the first supplied argument (before argument matching).

Typical usages are

seq(from, to)
seq(from, to, by = )
seq(from, to, length.out = )
seq(along.with = )
seq(from)
seq(length.out = )

The first form generates the sequence from, from/−1,..., to (identical to from:to).

The second form generates from, from+by,..., up to the sequence value less than or equal to to. Specifying to −from and by of opposite signs is an error. Note that the computed final value can go just beyond to to allow for rounding error, but is truncated to to. ('Just beyond' is by up to 10^{−10} times abs(from −to).)

The third generates a sequence of length.out equally spaced values from from to to. (length.out is usually abbreviated to length or len, and seq_len is much faster.)

The fourth form generates the integer sequence 1, 2,..., length(along.with). (along.with is usually abbreviated to along, and seq_along is much faster.)

The fifth form generates the sequence 1, 2,..., length(from) (as if argument along.with had been specified), unless the argument is numeric of length 1 when it is interpreted as 1:from (even for seq(θ) for compatibility with S). Using either seq_along or seq_len is much preferred (unless strict S compatibility is essential).

The final form generates the integer sequence 1, 2,..., length.out unless length.out = 0, when it generates integer(θ).

Very small sequences (with from −to of the order of 10^{−14} times the larger of the ends) will return from.
For `seq` (only), up to two of `from`, `to` and `by` can be supplied as complex values provided `length.out` or `along.with` is specified. More generally, the default method of `seq` will handle classed objects with methods for the Math, Ops and Summary group generics.

`seq.int`, `seq_along` and `seq_len` are primitive.

**Value**

`seq.int` and the default method of `seq` for numeric arguments return a vector of type "integer" or "double": programmers should not rely on which.

`seq_along` and `seq_len` return an integer vector, unless it is a long vector when it will be double.

**References**

**See Also**

The methods `seq.Date` and `seq.POSIXt`.

`:rep`, `sequence`, `row`, `col`.

**Examples**

```r
seq(0, 1, length.out = 11)
seq(stats::rnorm(20)) # effectively 'along'
seq(1, 9, by = 2)    # matches 'end'
seq(1, 9, by = pi)   # stays below 'end'
seq(1, 6, by = 3)
seq(1.575, 5.125, by = 0.05)
seq(17) # same as 1:17, or even better seq_len(17)
```

---

**seq.Date**  
*Generate Regular Sequences of Dates*

**Description**

The method for `seq` for objects of class class "Date" representing calendar dates.

**Usage**

```r
## S3 method for class 'Date'
seq(from, to, by, length.out = NULL, along.with = NULL, ...)
```

**Arguments**

- `from`: starting date. Required
- `to`: end date. Optional.
- `by`: increment of the sequence. Optional. See ‘Details’.
- `length.out`: integer, optional. Desired length of the sequence.
- `along.with`: take the length from the length of this argument.
- `...`: arguments passed to or from other methods.
The method for `seq` for date-time classes.

### Usage
```r
## S3 method for class 'POSIXt'
seq(from, to, by, length.out = NULL, along.with = NULL, ...)  
```

### Arguments

- `from`: starting date. Required.
- `to`: end date. Optional.
- `by`: increment of the sequence. Optional. See ‘Details’.
- `length.out`: integer, optional. Desired length of the sequence.
- `along.with`: take the length from the length of this argument.
- `...`: arguments passed to or from other methods.
Details
by can be specified in several ways.

- A number, taken to be in seconds.
- A object of class `difftime`
- A character string, containing one of "sec", "min", "hour", "day", "DSTday", "week", "month", "quarter" or "year". This can optionally be preceded by a (positive or negative) integer and a space, or followed by "s".

The difference between "day" and "DSTday" is that the former ignores changes to/from daylight savings time and the latter takes the same clock time each day. "week" ignores DST (it is a period of 144 hours), but "7 DSTdays" can be used as an alternative. "month" and "year" allow for DST.

The time zone of the result is taken from from: remember that GMT means UTC (and not the time zone of Greenwich, England) and so does not have daylight savings time.

Using "month" first advances the month without changing the day: if this results in an invalid day of the month, it is counted forward into the next month: see the examples.

Value
A vector of class "POSIXct".

See Also
DateTimeClasses

Examples
```
## first days of years
seq(ISOdate(1910,1,1), ISOdate(1999,1,1), "years")
## by month
seq(ISOdate(2000,1,1), by = "month", length.out = 12)
seq(ISOdate(2000,1,31), by = "month", length.out = 4)
## quarters
seq(ISOdate(1990,1,1), ISOdate(2000,1,1), by = "quarter") # or "3 months"
## days vs DSTdays: use c() to lose the time zone.
seq(c(ISOdate(2000,3,20)), by = "day", length.out = 10)
seq(c(ISOdate(2000,3,20)), by = "DSTday", length.out = 10)
seq(c(ISOdate(2000,3,20)), by = "7 DSTdays", length.out = 4)
```

sequence
Create A Vector of Sequences

Description
The default method for sequence generates the sequence seq(from[i], by = by[i], length.out = nvec[i]) for each element i in the parallel (and recycled) vectors from, by and nvec. It then returns the result of concatenating those sequences.

Usage
```
sequence(nvec, ...)
```
```
# Default S3 method:
sequence(nvec, from = 1L, by = 1L, ...)```
Arguments

**nvec** coerced to a non-negative integer vector each element of which specifies the length of a sequence.

**from** coerced to an integer vector each element of which specifies the first element of a sequence.

**by** coerced to an integer vector each element of which specifies the step size between elements of a sequence.

... additional arguments passed to methods.

Details

Negative values are supported for **from** and **by**. `sequence(nvec, from, by=0L)` is equivalent to `rep(from, each=nvec).

This function was originally implemented in R with fewer features, but it has since become more flexible, and the default method is implemented in C for speed.

Author(s)

Of the current version, Michael Lawrence based on code from the S4Vectors Bioconductor package

See Also

`gl`, `seq`, `rep`

Examples

```r
sequence(c(3, 2)) # the concatenated sequences 1:3 and 1:2.
#> [1] 1 2 3 1 2
sequence(c(3, 2), from=2L)
#> [1] 2 3 4 2 3
sequence(c(3, 2), from=2L, by=2L)
#> [1] 2 4 6 2 4
sequence(c(3, 2), by=c(-1L, 1L))
#> [1] 1 0 -1 1 2
```

serialize

**Simple Serialization Interface**

Description

A simple low-level interface for serializing to connections.

Usage

```r
serialize(object, connection, ascii, xdr = TRUE,
  version = NULL, refhook = NULL)

unserialize(connection, refhook = NULL)
```
Arguments

object    R object to serialize.
connection an open connection or (for serialize) NULL or (for unserialize) a raw vector (see ‘Details’).
ascii     a logical. If TRUE or NA, an ASCII representation is written; otherwise (default) a binary one. See also the comments in the help for save.
xdr       a logical: if a binary representation is used, should a big-endian one (XDR) be used?
version   the workspace format version to use. NULL specifies the current default version (3). The only other supported value is 2, the default from R 1.4.0 to R 3.5.0.
refhook   a hook function for handling reference objects.

Details

The function serialize serializes object to the specified connection. If connection is NULL then object is serialized to a raw vector, which is returned as the result of serialize.

Sharing of reference objects is preserved within the object but not across separate calls to serialize.

unserialize reads an object (as written by serialize) from connection or a raw vector.

The refhook functions can be used to customize handling of non-system reference objects (all external pointers and weak references, and all environments other than namespace and package environments and .GlobalEnv). The hook function for serialize should return a character vector for references it wants to handle; otherwise it should return NULL. The hook for unserialize will be called with character vectors supplied to serialize and should return an appropriate object.

For a text-mode connection, the default value of ascii is set to TRUE: only ASCII representations can be written to text-mode connections and attempting to use ascii = FALSE will throw an error.

The format consists of a single line followed by the data: the first line contains a single character: X for binary serialization and A for ASCII serialization, followed by a new line. (The format used is identical to that used by readRDS.)

As almost all systems in current use are little-endian, xdr = FALSE can be used to avoid byte-shuffling at both ends when transferring data from one little-endian machine to another (or between processes on the same machine). Depending on the system, this can speed up serialization and unserialization by a factor of up to 3x.

Value

For serialize, NULL unless connection = NULL, when the result is returned in a raw vector.

For unserialize an R object.

Warning

These functions have provided a stable interface since R 2.4.0 (when the storage of serialized objects was changed from character to raw vectors). However, the serialization format may change in future versions of R, so this interface should not be used for long-term storage of R objects.

On 32-bit platforms a raw vector is limited to $2^{31} - 1$ bytes, but R objects can exceed this and their serializations will normally be larger than the objects.
See Also

`saveRDS` for a more convenient interface to serialize an object to a file or connection. `save` and `load` to serialize and restore one or more named objects. The ‘R Internals’ manual for details of the format used.

Examples

```r
x <- serialize(list(1,2,3), NULL)
unserialize(x)

## see also the examples for saveRDS
```

sets Set Operations

Description

Performs set union, intersection, (asymmetric!) difference, equality and membership on two vectors.

Usage

```r
union(x, y)
intersect(x, y)
setdiff(x, y)
setequal(x, y)

is.element(el, set)
```

Arguments

```r
x, y, el, set vectors (of the same mode) containing a sequence of items (conceptually) with no duplicated values.
```

Details

Each of `union`, `intersect`, `setdiff` and `setequal` will discard any duplicated values in the arguments, and they apply `as.vector` to their arguments (and so in particular coerce factors to character vectors).

`is.element(x,y)` is identical to `x %in% y`.

Value

A vector of the same mode as `x` or `y` for `setdiff` and `intersect`, respectively, and of a common mode for `union`.

A logical scalar for `setequal` and a logical of the same length as `x` for `is.element`.

See Also

`%in%`

`'plotmath'` for the use of `union` and `intersect` in plot annotation.
Examples

```r
(x <- c(sort(sample(1:20, 9)), NA))
(y <- c(sort(sample(3:23, 7)), NA))
union(x, y)
intersect(x, y)
setdiff(x, y)
setdiff(y, x)
setequal(x, y)
```

```r
## True for all possible x & y:
setequal(union(x, y),
         c(setdiff(x, y), intersect(x, y), setdiff(y, x)))
```

```r
is.element(x, y) # length 10
is.element(y, x) # length 8
```

---

**setTimeLimit**

*Set CPU and/or Elapsed Time Limits*

**Description**

Functions to set CPU and/or elapsed time limits for top-level computations or the current session.

**Usage**

```r
setTimeLimit(cpu = Inf, elapsed = Inf, transient = FALSE)
setSessionTimeLimit(cpu = Inf, elapsed = Inf)
```

**Arguments**

- `cpu`, `elapsed` double (of length one). Set a limit on the total or elapsed cpu time in seconds, respectively.
- `transient` logical. If TRUE, the limits apply only to the rest of the current computation.

**Details**

`setTimeLimit` sets limits which apply to each top-level computation, that is a command line (including any continuation lines) entered at the console or from a file. If it is called from within a computation the limits apply to the rest of the computation and (unless transient = TRUE) to subsequent top-level computations.

`setSessionTimeLimit` sets limits for the rest of the session. Once a session limit is reached it is reset to Inf.

Setting any limit has a small overhead – well under 1% on the systems measured.

Time limits are checked whenever a user interrupt could occur. This will happen frequently in R code and during `Sys.sleep`, but only at points in compiled C and Fortran code identified by the code author.

‘Total cpu time’ includes that used by child processes where the latter is reported.
showConnections  

**Display Connections**

**Description**

Display aspects of connections.

**Usage**

```r
showConnections(all = FALSE)
getConnection(what)
closeAllConnections()

stdin()
stdout()
stderr()
nullfile()

isatty(con)
```

**Arguments**

- `all` logical: if true all connections, including closed ones and the standard ones are displayed. If false only open user-created connections are included.
- `what` integer: a row number of the table given by `showConnections`.
- `con` a connection.

**Details**

`stdin()`, `stdout()` and `stderr()` are standard connections corresponding to input, output and error on the console respectively (and not necessarily to file streams). They are text-mode connections of class "terminal" which cannot be opened or closed, and are read-only, write-only and write-only respectively. The `stdout()` and `stderr()` connections can be re-directed by `sink` (and in some circumstances the output from `stdout()` can be split: see the help page).

The encoding for `stdin()` when redirected can be set by the command-line flag ‘--encoding’.

`nullfile()` returns filename of the null device (“/dev/null” on Unix, "nul:" on Windows).

`showConnections` returns a matrix of information. If a connection object has been lost or forgotten, `getConnection` will take a row number from the table and return a connection object for that connection, which can be used to close the connection, for example. However, if there is no R level object referring to the connection it will be closed automatically at the next garbage collection (except for `gzcon` connections).

`closeAllConnections` closes (and destroys) all user connections, restoring all `sink` diversions as it does so.

`isatty` returns true if the connection is one of the class "terminal" connections and it is apparently connected to a terminal, otherwise false. This may not be reliable in embedded applications, including GUI consoles.
Value

stdin(), stdout() and stderr() return connection objects.
showConnections returns a character matrix of information with a row for each connection, by
default only for open non-standard connections.
getConnection returns a connection object, or NULL.

Note

stdin() refers to the ‘console’ and not to the C-level ‘stdin’ of the process. The distinction matters
in GUI consoles (which may not have an active ‘stdin’, and if they do it may not be connected
to console input), and also in embedded applications. If you want access to the C-level file stream
‘stdin’, use file("stdin").

When R is reading a script from a file, the file is the ‘console’: this is traditional usage to allow
in-line data (see ‘An Introduction to R’ for an example).

closeConnections

Examples

showConnections(all = TRUE)
## Not run:
textConnection(letters)
# oops, I forgot to record that one
showConnections()
# class description mode text isopen can read can write
#3 "letters" "textConnection" "r" "text" "opened" "yes" "no"
mycon <- getConnection(3)
## End(Not run)
c(isatty(stdin())), isatty(stdout()), isatty(stderr()))

shQuote

Quote Strings for Use in OS Shells

Description

Quote a string to be passed to an operating system shell.

Usage

shQuote(string, type = c("sh", "csh", "cmd", "cmd2"))

Arguments

string a character vector, usually of length one.
type character: the type of shell quoting. Partial matching is supported. "cmd" and
"cmd2" refer to the Windows shell. "cmd" is the default under Windows.
Details

The default type of quoting supported under Unix-alikes is that for the Bourne shell `sh`. If the string does not contain single quotes, we can just surround it with single quotes. Otherwise, the string is surrounded in double quotes, which suppresses all special meanings of metacharacters except dollar, backquote and backslash, so these (and of course double quote) are preceded by backslash. This type of quoting is also appropriate for bash, ksh and zsh.

The other type of quoting is for the C-shell (csh and tcsh). Once again, if the string does not contain single quotes, we can just surround it with single quotes. If it does contain single quotes, we can use double quotes provided it does not contain dollar or backquote (and we need to escape backslash, exclamation mark and double quote). As a last resort, we need to split the string into pieces not containing single quotes and surround each with single quotes, and the single quotes with double quotes.

In Windows, command line interpretation is done by the application as well as the shell. It may depend on the compiler used: Microsoft's rules for the C run-time are given at [https://msdn.microsoft.com/library/ms808421](https://msdn.microsoft.com/library/ms808421). It may depend on the whim of the programmer of the application: check its documentation. The `type = "cmd"` quoting surrounds the string by double quotes and escapes internal double quotes by a backslash. As Windows path names cannot contain double quotes, this makes shQuote safe for use with many applications when used with `system` or `system2`. The Windows cmd.exe shell (used by default with `shell`) uses `type = "cmd2"` quoting: special characters are prefixed with "^". In some cases, two types of quoting should be used: first for the application, and then `type = "cmd2"` for cmd.exe. See the examples below.

shell(shQuote(paste("perl -e",
shQuote(perlcmd, type = "cmd")),
type = "cmd2"))

## End(Not run)
**sign**  
*Sign Function*

**Description**

`sign` returns a vector with the signs of the corresponding elements of `x` (the sign of a real number is 1, 0, or \(-1\) if the number is positive, zero, or negative, respectively).

Note that `sign` does not operate on complex vectors.

**Usage**

```r
sign(x)
```

**Arguments**

- `x` a numeric vector

**Details**

This is an internal generic primitive function: methods can be defined for it directly or via the `Math` group generic.

**See Also**

`abs`

**Examples**

```r
sign(pi)  # == 1
sign(-2:3) # -1 -1 0 1 1 1
```

**Signals**  
*Interrupting Execution of R*

**Description**

On receiving SIGUSR1 `R` will save the workspace and quit. SIGUSR2 has the same result except that the `.Last` function and `on.exit` expressions will not be called.

**Usage**

```r
kill -USR1 pid
kill -USR2 pid
```

**Arguments**

- `pid` The process ID of the `R` process.
sink

Send R Output to a File

Description

sink diverts R output to a connection (and stops such diversions).

sink.number() reports how many diversions are in use.

sink.number(type = "message") reports the number of the connection currently being used for error messages.

Usage

sink(file = NULL, append = FALSE, type = c("output", "message"), split = FALSE)

sink.number(type = c("output", "message"))

Arguments

file
append
type
split

da writable connection or a character string naming the file to write to, or NULL to stop sink-ing.

logical. If TRUE, output will be appended to file; otherwise, it will overwrite the contents of file.

character string. Either the output stream or the messages stream. The name will be partially matched so can be abbreviated.

logical: if TRUE, output will be sent to the new sink and to the current output stream, like the Unix program tee.

Details

sink diverts R output to a connection (and must be used again to finish such a diversion, see below!). If file is a character string, a file connection with that name will be established for the duration of the diversion.

Normal R output (to connection stdout) is diverted by the default type = "output". Only prompts and (most) messages continue to appear on the console. Messages sent to stderr() (including those from message, warning and stop) can be diverted by sink(type = "message") (see below).

Warning

It is possible that one or more R objects will be undergoing modification at the time the signal is sent. These objects could be saved in a corrupted form.

See Also

Sys.getpid to report the process ID for future use.
sink() or sink(file = NULL) ends the last diversion (of the specified type). There is a stack of diversions for normal output, so output reverts to the previous diversion (if there was one). The stack is of up to 21 connections (20 diversions).

If file is a connection it will be opened if necessary (in "wt" mode) and closed once it is removed from the stack of diversions.

split = TRUE only splits R output (via Rvprintf) and the default output from writeLines: it does not split all output that might be sent to stdout().

Sink-ing the messages stream should be done only with great care. For that stream file must be an already open connection, and there is no stack of connections.

If file is a character string, the file will be opened using the current encoding. If you want a different encoding (e.g., to represent strings which have been stored in UTF-8), use a file connection — but some ways to produce R output will already have converted such strings to the current encoding.

Value

sink returns NULL.

For sink.number() the number (0, 1, 2, . . .) of diversions of output in place.

For sink.number("message") the connection number used for messages, 2 if no diversion has been used.

Warning

Do not use a connection that is open for sink for any other purpose. The software will stop you closing one such inadvertently.

Do not sink the messages stream unless you understand the source code implementing it and hence the pitfalls.

See Also

capture.output

Examples

sink("sink-examp.txt")
i <- 1:10
outer(i, i, "+")
sink()

## capture all the output to a file.
zz <- file("all.Rout", open = "wt")
sink(zz)
sink(zz, type = "message")
try(log("a"))
## revert output back to the console -- only then access the file!
sink(type = "message")
slice.index

Slice Indexes in an Array

Description
Returns a matrix of integers indicating the number of their slice in a given array.

Usage
slice.index(x, MARGIN)

Arguments
x
an array. If x has no dimension attribute, it is considered a one-dimensional array.

MARGIN
an integer vector giving the dimension numbers to slice by.

Details
If MARGIN gives a single dimension, then all elements of slice number i with respect to this have value i. In general, slice numbers are obtained by numbering all combinations of indices in the dimensions given by MARGIN in column-major order. I.e., with \( m_1, \ldots, m_k \) the dimension numbers (elements of MARGIN) sliced by and \( d_{m_1}, \ldots, d_{m_k} \) the corresponding extents, and \( n_1 = 1, n_2 = d_{m_1}, \ldots, n_k = d_{m_1} \cdots d_{m_{k-1}}, \) the number of the slice where dimension \( m_1 \) has value \( i_1, \ldots, \) dimension \( m_k \) has value \( i_k \) is \( 1 + n_1(i_1 - 1) + \cdots + n_k(i_k - 1) \).

Value
An integer array \( y \) with dimensions corresponding to those of \( x \).

See Also
row and col for determining row and column indexes; in fact, these are special cases of slice.index corresponding to MARGIN equal to 1 and 2, respectively when \( x \) is a matrix.

Examples
\[
x <- array(1:24, c(2, 3, 4))
slice.index(x, 2)
slice.index(x, c(1, 3))
## When slicing by dimensions 1 and 3, slice index 5 is obtained for
## dimension 1 has value 1 and dimension 3 has value 3 (see above):
which(slice.index(x, c(1, 3)) == 5, arr.ind = TRUE)
\]
**slotOp**

*Extract or Replace A Slot*

**Description**

Extract or replace the contents of a slot in an object with a formal (S4) class structure.

**Usage**

```r
object@name
object@name <- value
```

**Arguments**

- **object**: An object from a formally defined (S4) class.
- **name**: The character-string name of the slot, quoted or not. Must be the name of a slot in the definition of the class of object.
- **value**: A replacement value for the slot, which must be from a class compatible with the class defined for this slot in the definition of the class of object.

**Details**

These operators support the formal classes of package `methods`, and are enabled only when package `methods` is loaded (as per default). See `slot` for further details, in particular for the differences between `slot()` and the `@` operator.

It is checked that `object` is an S4 object (see `isS4`), and it is an error to attempt to use `@` on any other object. (There is an exception for `name .Data` for internal use only.) The replacement operator checks that the slot already exists on the object (which it should if the object is really from the class it claims to be).

These are internal generic operators: see `InternalMethods`.

**Value**

The current contents of the slot.

**See Also**

`Extract`, `slot`
socketSelect  
*Wait on Socket Connections*

**Description**

Waits for the first of several socket connections and server sockets to become available.

**Usage**

```r
socketSelect(socklist, write = FALSE, timeout = NULL)
```

**Arguments**

- `socklist`: list of open socket connections and server sockets.
- `write`: logical. If TRUE wait for corresponding socket to become available for writing; otherwise wait for it to become available for reading or for accepting an incoming connection (server sockets).
- `timeout`: numeric or NULL. Time in seconds to wait for a socket to become available; NULL means wait indefinitely.

**Details**

The values in `write` are recycled if necessary to make up a logical vector the same length as `socklist`. Socket connections can appear more than once in `socklist`; this can be useful if you want to determine whether a socket is available for reading or writing.

**Value**

Logical the same length as `socklist` indicating whether the corresponding socket connection is available for output or input, depending on the corresponding value of `write`. Server sockets can only become available for input.

**Examples**

```r
## Not run:
## test whether socket connection s is available for writing or reading
socketSelect(list(s, s), c(TRUE, FALSE), timeout = 0)
## End(Not run)
```

---

**solve**  
*Solve a System of Equations*

**Description**

This generic function solves the equation `a %*% x = b` for `x`, where `b` can be either a vector or a matrix.
solve

Usage

solve(a, b, ...)  
## Default S3 method:
solve(a, b, tol, LINPACK = FALSE, ...)

Arguments

a
  a square numeric or complex matrix containing the coefficients of the linear system. Logical matrices are coerced to numeric.

b
  a numeric or complex vector or matrix giving the right-hand side(s) of the linear system. If missing, b is taken to be an identity matrix and solve will return the inverse of a.

tol

LINPACK
  logical. Defunct and an error.

...
  further arguments passed to or from other methods

Details

a or b can be complex, but this uses double complex arithmetic which might not be available on all platforms.

The row and column names of the result are taken from the column names of a and of b respectively. If b is missing the column names of the result are the row names of a. No check is made that the column names of a and the row names of b are equal.

For back-compatibility a can be a (real) QR decomposition, although qr.solve should be called in that case. qr.solve can handle non-square systems.

Unsuccessful results from the underlying LAPACK code will result in an error giving a positive error code: these can only be interpreted by detailed study of the FORTRAN code.

Source

The default method is an interface to the LAPACK routines DGESV and ZGESV.

LAPACK is from https://www.netlib.org/lapack/.

round(sh8 %*% h8, 3)

A <- hilbert(4)
A[] <- as.complex(A)
## might not be supported on all platforms
try(solve(A))

---

Sort (or order) a vector or factor (partially) into ascending or descending order. For ordering along more than one variable, e.g., for sorting data frames, see `order`.

Usage

```r
sort(x, decreasing = FALSE, ...)  
## Default S3 method:  
sort(x, decreasing = FALSE, na.last = NA, ...)  
sort.int(x, partial = NULL, na.last = NA, decreasing = FALSE,  
    method = c("auto", "shell", "quick", "radix"), index.return = FALSE)
```

Arguments

- **x**: for `sort` an R object with a class or a numeric, complex, character or logical vector. For `sort.int`, a numeric, complex, character or logical vector, or a factor.
- **decreasing**: logical. Should the sort be increasing or decreasing? For the "radix" method, this can be a vector of length equal to the number of arguments in `...`. For the other methods, it must be length one. Not available for partial sorting.
- **...**: arguments to be passed to or from methods or (for the default methods and objects without a class) to `sort.int`.
- **na.last**: for controlling the treatment of NAs. If TRUE, missing values in the data are put last; if FALSE, they are put first; if NA, they are removed.
- **partial**: NULL or a vector of indices for partial sorting.
- **method**: character string specifying the algorithm used. Not available for partial sorting. Can be abbreviated.
- **index.return**: logical indicating if the ordering index vector should be returned as well. Supported by `method = "radix"` for any `na.last` mode and data type, and the other methods when `na.last = NA` (the default) and fully sorting non-factors.
sort is a generic function for which methods can be written, and sort.int is the internal method which is compatible with S if only the first three arguments are used.

The default sort method makes use of order for classed objects, which in turn makes use of the generic function xtfrm (and can be slow unless a xtfrm method has been defined or is.numeric(x) is true).

Complex values are sorted first by the real part, then the imaginary part.

The "auto" method selects "radix" for short (less than $2^{31}$ elements) numeric vectors, integer vectors, logical vectors and factors; otherwise, "shell".

Except for method "radix", the sort order for character vectors will depend on the collating sequence of the locale in use: see Comparison. The sort order for factors is the order of their levels (which is particularly appropriate for ordered factors).

If partial is not NULL, it is taken to contain indices of elements of the result which are to be placed in their correct positions in the sorted array by partial sorting. For each of the result values in a specified position, any values smaller than that one are guaranteed to have a smaller index in the sorted array and any values which are greater are guaranteed to have a bigger index in the sorted array. (This is included for efficiency, and many of the options are not available for partial sorting. It is only substantially more efficient if partial has a handful of elements, and a full sort is done (a Quicksort if possible) if there are more than 10.) Names are discarded for partial sorting.

Method "shell" uses Shellsort (an $O(n^{4/3})$ variant from Sedgewick (1986)). If x has names a stable modification is used, so ties are not reordered. (This only matters if names are present.)

Method "quick" uses Singleton (1969)'s implementation of Hoare's Quicksort method and is only available when x is numeric (double or integer) and partial is NULL. (For other types of x Shellsort is used, silently.) It is normally somewhat faster than Shellsort (perhaps 50% faster on vectors of length a million and twice as fast at a billion) but has poor performance in the rare worst case. (Peto's modification using a pseudo-random midpoint is used to make the worst case rarer.) This is not a stable sort, and ties may be reordered.

Method "radix" relies on simple hashing to scale time linearly with the input size, i.e., its asymptotic time complexity is $O(n)$. The specific variant and its implementation originated from the data.table package and are due to Matt Dowle and Arun Srinivasan. For small inputs (< 200), the implementation uses an insertion sort ($O(n^2)$) that operates in-place to avoid the allocation overhead of the radix sort. For integer vectors of range less than 100,000, it switches to a simpler and faster linear time counting sort. In all cases, the sort is stable; the order of ties is preserved. It is the default method for integer vectors and factors.

The "radix" method generally outperforms the other methods, especially for character vectors and small integers. Compared to quick sort, it is slightly faster for vectors with large integer or real values (but unlike quick sort, radix is stable and supports all na.last options). The implementation is orders of magnitude faster than shell sort for character vectors, in part thanks to clever use of the internal CHARSXP table.

However, there are some caveats with the radix sort:

- If x is a character vector, all elements must share the same encoding. Only UTF-8 (including ASCII) and Latin-1 encodings are supported. Collation always follows the "C" locale.
- Long vectors (with more than $2^{32}$ elements) and complex vectors are not supported yet.

Value

For sort, the result depends on the S3 method which is dispatched. If x does not have a class sort.int is used and it description applies. For classed objects which do not have a specific
method the default method will be used and is equivalent to \( x[\text{order}(x, \ldots)] \): this depends on
the class having a suitable method for \( [ \) (and also that \text{order} will work, which requires a \text{xtfrm}
method).

For \text{sort.int} the value is the sorted vector unless \text{index.return} is true, when the result is a list
with components named \( x \) and \( ix \) containing the sorted numbers and the ordering index vector. In
the latter case, if \text{method} == "quick" ties may be reversed in the ordering (Unlike \text{sort.list}) as
quicksort is not stable. For \text{method} == "radix", \text{index.return} is supported for all \text{na.last} modes.
The other methods only support \text{index.return} when \text{na.last} is \( \text{NA} \). The index vector refers to
element numbers \text{after removal of} \( \text{NAs} \): see \text{order} if you want the original element numbers.

All attributes are removed from the return value (see Becker et al, 1988, p.146) except names,
which are sorted. (If \text{partial} is specified even the names are removed.) Note that this means that
the returned value has no class, except for factors and ordered factors (which are treated specially
and whose result is transformed back to the original class).

source

Read R Code from a File, a Connection or Expressions

### Description

source causes R to accept its input from the named file or URL or connection or expressions directly. Input is read and parsed from that file until the end of the file is reached, then the parsed expressions are evaluated sequentially in the chosen environment.

withAutoprint(exprs) is a wrapper for source(exprs = exprs,..) with different defaults. Its main purpose is to evaluate and auto-print expressions as if in a toplevel context, e.g, as in the R console.

### Usage

source(file, local = FALSE, echo = verbose, print.eval = echo, 
       exprs, spaced = use_file, 
       verbose = getOption("verbose"), 
       prompt.echo = getOption("prompt"),
       max.deparse.length = 150, width.cutoff = 60L, 
       deparseCtrl = "showAttributes", 
       chdir = FALSE, 
       encoding = getOption("encoding"), 
       continue.echo = getOption("continue"),
       skip.echo = 0, keep.source = getOption("keep.source"))

withAutoprint(exprs, evaluated = FALSE, local = parent.frame(), 
              print. = TRUE, echo = TRUE, max.deparse.length = Inf, 
              width.cutoff = max(20, getOption("width")), 
              deparseCtrl = c("keepInteger", "showAttributes", "keepNA"),
              ...)
Arguments

- **file**: a connection or a character string giving the pathname of the file or URL to read from. "" indicates the connection `stdin()`.
- **local**: TRUE, FALSE or an environment, determining where the parsed expressions are evaluated. FALSE (the default) corresponds to the user's workspace (the global environment) and TRUE to the environment from which `source` is called.
- **echo**: logical; if TRUE, each expression is printed after parsing, before evaluation.
- **print.eval.print**: logical; if TRUE, the result of `eval(i)` is printed for each expression `i`; defaults to the value of `echo`.
- **exprs**: for `source()` and `withAutoprint(*, evaluated=TRUE)`: instead of specifying `file`, an expression, call, or list of call's, but not an unevaluated "expression".
- **evaluated**: logical indicating that `exprs` is passed to `source(exprs= *)` and hence must be evaluated, i.e., a formal expression, call or list of calls.
- **spaced**: logical indicating if newline (hence empty line) should be printed before each expression (when `echo = TRUE`).
- **verbose**: if TRUE, more diagnostics (than just `echo = TRUE`) are printed during parsing and evaluation of input, including extra info for each expression.
- **prompt.echo**: character; gives the prompt to be used if `echo = TRUE`.
- **max.deparse.length**: integer; is used only if `echo` is TRUE and gives the maximal number of characters output for the deparse of a single expression.
- **width.cutoff**: integer, passed to `deparse()` which is used (only) when there are no source references.
- **deparseCtrl**: character vector, passed as control to `deparse()`, see also `.deparseOpts`. In R version <= 3.3.x, this was hardcoded to "showAttributes", which is the default currently; `deparseCtrl = "all"` may be preferable, when strict back compatibility is not of importance.
- **chdir**: logical; if TRUE and `file` is a pathname, the R working directory is temporarily changed to the directory containing `file` for evaluating.
- **encoding**: character vector. The encoding(s) to be assumed when `file` is a character string: see `file`. A possible value is "unknown" when the encoding is guessed: see the "Encodings" section.
- **continue.echo**: character; gives the prompt to use on continuation lines if `echo = TRUE`.
- **skip.echo**: integer; how many comment lines at the start of the file to skip if `echo = TRUE`.
- **keep.source**: logical: should the source formatting be retained when echoing expressions, if possible?
- **...**: (for `withAutoprint()`:) further (non-file related) arguments to be passed to `source(.)`.

Details

Note that running code via `source` differs in a few respects from entering it at the R command line. Since expressions are not executed at the top level, auto-printing is not done. So you will need
to include explicit print calls for things you want to be printed (and remember that this includes plotting by `lattice`, FAQ Q7.22). Since the complete file is parsed before any of it is run, syntax errors result in none of the code being run. If an error occurs in running a syntactically correct script, anything assigned into the workspace by code that has been run will be kept (just as from the command line), but diagnostic information such as `traceback()` will contain additional calls to `withVisible`.

All versions of R accept input from a connection with end of line marked by LF (as used on Unix), CRLF (as used on DOS/Windows) or CR (as used on classic Mac OS) and map this to newline. The final line can be incomplete, that is missing the final end-of-line marker.

If `keep.source` is true (the default in interactive use), the source of functions is kept so they can be listed exactly as input.

Unlike input from a console, lines in the file or on a connection can contain an unlimited number of characters.

When `skip.echo > 0`, that many comment lines at the start of the file will not be echoed. This does not affect the execution of the code at all. If there are executable lines within the first `skip.echo` lines, echoing will start with the first of them.

If `echo` is true and a deparsed expression exceeds `max.deparse.length`, that many characters are output followed by .... [TRUNCATED].

**Encodings**

By default the input is read and parsed in the current encoding of the R session. This is usually what it required, but occasionally re-encoding is needed, e.g. if a file from a UTF-8-using system is to be read on Windows (or vice versa).

The rest of this paragraph applies if `file` is an actual filename or URL (and not "" nor a connection). If `encoding = "unknown"`, an attempt is made to guess the encoding: the result of `localeToCharset()` is used as a guide. If encoding has two or more elements, they are tried in turn until the file/URL can be read without error in the trial encoding. If an actual encoding is specified (rather than the default or "unknown") in a Latin-1 or UTF-8 locale then character strings in the result will be translated to the current encoding and marked as such (see Encoding).

If `file` is a connection (including one specified by ""), it is not possible to re-encode the input inside `source`, and so the encoding argument is just used to mark character strings in the parsed input in Latin-1 and UTF-8 locales: see `parse`.

**References**

**Examples**

```r
someCond <- 7 > 6
## want an if-clause to behave "as top level" wrt auto-printing :
## (all should look "as on top level", e.g. non-assignments should print:)
if(someCond) withAutoprint(
```
x <- 1:12
x-1
(y <- (x-5)^2)
z <- y
z - 10
}

## If you want to source() a bunch of files, something like
## the following may be useful:
sourceDir <- function(path, trace = TRUE, ...) {
  for (nm in list.files(path, pattern = "[.][RrSsQq]$")) {
    if(trace) cat(nm,":")
    source(file.path(path, nm), ...)
    if(trace) cat("n")
  }
}
suppressWarnings( rm(x,y) ) # remove 'x' or 'y' from global env
withAutoprint({ x <- 1:2; cat("x=",x,"n"); y <- x^2 })
## x and y now exist:
stopifnot(identical(x, 1:2), identical(y, x^2))

withAutoprint({ formals(sourceDir); body(sourceDir) },
  max.dep = 20, verbose = TRUE)

---

## Special Functions of Mathematics

### Description

Special mathematical functions related to the beta and gamma functions.

### Usage

- `beta(a, b)`
- `lbeta(a, b)`
- `gamma(x)`
- `lgamma(x)`
- `psigamma(x, deriv = 0)`
- `digamma(x)`
- `trigamma(x)`
- `choose(n, k)`
- `lchoose(n, k)`
- `factorial(x)`
- `lfactorial(x)`

### Arguments

- `a, b` non-negative numeric vectors.
- `x, n` numeric vectors.
- `k, deriv` integer vectors.
Details

The functions beta and lbeta return the beta function and the natural logarithm of the beta function,

\[ B(a, b) = \frac{\Gamma(a)\Gamma(b)}{\Gamma(a + b)}. \]

The formal definition is

\[ B(a, b) = \int_0^1 t^{a-1}(1 - t)^{b-1} dt \]

(Abramowitz and Stegun section 6.2.1, page 258). Note that it is only defined in \( \mathbb{R} \) for non-negative a and b, and is infinite if either is zero.

The functions gamma and lgamma return the gamma function \( \Gamma(x) \) and the natural logarithm of the absolute value of the gamma function. The gamma function is defined by (Abramowitz and Stegun section 6.1.1, page 255)

\[ \Gamma(x) = \int_0^\infty t^{x-1}e^{-t} dt \]

for all real \( x \) except zero and negative integers (when NaN is returned). There will be a warning on possible loss of precision for values which are too close (within about \( 10^{-8} \)) to a negative integer less than ‘-10’.

factorial(x) (x! for non-negative integer x) is defined to be gamma(x+1) and lfactorial to be lgamma(x+1).

The functions digamma and trigamma return the first and second derivatives of the logarithm of the gamma function. psigamma(x, deriv) (deriv >= 0) computes the deriv-th derivative of \( \psi(x) \).

\[ \psi(x) = \frac{d}{dx} \ln \Gamma(x) = \frac{\Gamma'(x)}{\Gamma(x)} \]

\( \psi \) and its derivatives, the psigamma() functions, are often called the ‘polygamma’ functions, e.g. in Abramowitz and Stegun (section 6.4.1, page 260); and higher derivatives (deriv = 2:4) have occasionally been called ‘tetragamma’, ‘pentagamma’, and ‘hexagamma’.

The functions choose and lchoose return binomial coefficients and the logarithms of their absolute values. Note that choose(n,k) is defined for all real numbers n and integer k. For k ≥ 1 it is defined as \( n(n-1)\cdots(n-k+1)/k! \), as 1 for k = 0 and as 0 for negative k. Non-integer values of k are rounded to an integer, with a warning.

choose(*,k) uses direct arithmetic (instead of [l]gamma calls) for small k, for speed and accuracy reasons. Note the function combn (package utils) for enumeration of all possible combinations.

The gamma, lgamma, digamma and trigamma functions are internal generic primitive functions: methods can be defined for them individually or via the Math group generic.

Source

gamma, lgamma, beta and lbeta are based on C translations of Fortran subroutines by W. Fullerton of Los Alamos Scientific Laboratory (now available as part of SLATEC).

digamma, trigamma and psigamma are based on

---

### split

**Divide into Groups and Reassemble**

#### Description

split divides the data in the vector `x` into the groups defined by `f`. The replacement forms replace values corresponding to such a division. `unsplit` reverses the effect of `split`.

#### Usage

```r
split(x, f, drop = FALSE, ...) 
## Default S3 method: split(x, f, drop = FALSE, sep = ".", lex.order = FALSE, ...)

split(x, f, drop = FALSE, ...) <- value
unsplit(value, f, drop = FALSE)
```

#### Arguments

- `x` vector or data frame containing values to be divided into groups.
- `f` a ‘factor’ in the sense that `as.factor(f)` defines the grouping, or a list of such factors in which case their interaction is used for the grouping.
- `drop` logical indicating if levels that do not occur should be dropped (if `f` is a factor or a list).
- `value` a list of vectors or data frames compatible with a splitting of `x`. Recycling applies if the lengths do not match.
- `sep` character string, passed to `interaction` in the case where `f` is a list.
- `lex.order` logical, passed to `interaction` when `f` is a list.
- `...` further potential arguments passed to methods.
split and split<- are generic functions with default and data.frame methods. The data frame method can also be used to split a matrix into a list of matrices, and the replacement form likewise, provided they are invoked explicitly.

unsplit works with lists of vectors or data frames (assumed to have compatible structure, as if created by split). It puts elements or rows back in the positions given by \( f \). In the data frame case, row names are obtained by unsplitting the row name vectors from the elements of value.

\( f \) is recycled as necessary and if the length of \( x \) is not a multiple of the length of \( f \) a warning is printed.

Any missing values in \( f \) are dropped together with the corresponding values of \( x \).

The default method calls **interaction** when \( f \) is a **list**. If the levels of the factors contain ‘.’ the factors may not be split as expected, unless \( \text{sep} \) is set to string not present in the factor **levels**.

**Value**

The value returned from **split** is a list of vectors containing the values for the groups. The components of the list are named by the levels of \( f \) (after converting to a factor, or if already a factor and \( \text{drop} = \text{TRUE} \), dropping unused levels).

The replacement forms return their right hand side. **unsplit** returns a vector or data frame for which **split**(\( x, f \)) equals value.

**References**

cut to categorize numeric values.

strsplit to split strings.

**Examples**

```r
require(stats); require(graphics)

n <- 10; nn <- 100
g <- factor(round(n * runif(n * nn)))
x <- rnorm(n * nn) + sqrt(as.numeric(g))
xg <- split(x, g)
boxplot(xg, col = "lavender", notch = TRUE, varwidth = TRUE)
sapply(xg, length)
sapply(xg, mean)

### Calculate ‘z-scores’ by group (standardize to mean zero, variance one)
z <- unsplit(lapply(split(x, g), scale), g)

# or

zz <- x
split(zz, g) <- lapply(split(x, g), scale)

# and check that the within-group std dev is indeed one
tapply(z, g, sd)
tapply(zz, g, sd)
```

### data frame variation

## Notice that assignment form is not used since a variable is being added

g <- airquality$Month
l <- split(airquality, g)
l <- lapply(l, transform, Oz.Z = scale(Ozone))
aq2 <- unsplit(l, g)
head(aq2)

with(aq2, tapply(Oz.Z, Month, sd, na.rm = TRUE))

### Split a matrix into a list by columns

ma <- cbind(x = 1:10, y = (-4:5)^2)
split(ma, col(ma))
split(1:10, 1:2)

---

**sprintf**

**Use C-style String Formatting Commands**

**Description**

A wrapper for the C function `sprintf`, that returns a character vector containing a formatted combination of text and variable values.

**Usage**

```r
sprintf(fmt, ...)
gettextf(fmt, ..., domain = NULL)
```

**Arguments**

- `fmt` a character vector of format strings, each of up to 8192 bytes.
- `...` values to be passed into `fmt`. Only logical, integer, real and character vectors are supported, but some coercion will be done: see the ‘Details’ section. Up to 100.
- `domain` see `gettext`.

**Details**

`sprintf` is a wrapper for the system `sprintf` C-library function. Attempts are made to check that the mode of the values passed match the format supplied, and R’s special values (`NA`, `Inf`, `-Inf` and `NaN`) are handled correctly.

`gettextf` is a convenience function which provides C-style string formatting with possible translation of the format string.

The arguments (including `fmt`) are recycled if possible a whole number of times to the length of the longest, and then the formatting is done in parallel. Zero-length arguments are allowed and will give a zero-length result. All arguments are evaluated even if unused, and hence some types (e.g., "symbol" or "language", see `typeof`) are not allowed.
The following is abstracted from Kernighan and Ritchie (see References): however the actual implementation will follow the C99 standard and fine details (especially the behaviour under user error) may depend on the platform. References to numbered arguments come from POSIX.

The string `fmt` contains normal characters, which are passed through to the output string, and also conversion specifications which operate on the arguments provided through `...`. The allowed conversion specifications start with a `%` and end with one of the letters in the set `aAdifeEgGosxX%`. These letters denote the following types:

- `d`, `i`, `o`, `x`, `X`: Integer value, `o` being octal, `x` and `X` being hexadecimal (using the same case for `a-f` as the code). Numeric variables with exactly integer values will be coerced to integer. Formats `d` and `i` can also be used for logical variables, which will be converted to 0, 1 or `NA`.

- `f`: Double precision value, in “fixed point” decimal notation of the form `[-]mmm.ddd`. The number of decimal places (“d”) is specified by the precision: the default is 6; a precision of 0 suppresses the decimal point. Non-finite values are converted to `NA`, `NaN` or (perhaps a sign followed by) `Inf`.

- `e`, `E`: Double precision value, in “exponential” decimal notation of the form `[-]m.ddde[+-]xx` or `[-]m.dddE[+-]xx`.

- `g`, `G`: Double precision value, in `%e` or `%E` format if the exponent is less than -4 or greater than or equal to the precision, and `%f` format otherwise. (The precision (default 6) specifies the number of significant digits here, whereas in `%f`, `%e`, it is the number of digits after the decimal point.)

- `a`, `A`: Double precision value, in binary notation of the form `[-]0xh.hhhp[+-]d`. This is a binary fraction expressed in hex multiplied by a (decimal) power of 2. The number of hex digits after the decimal point is specified by the precision: the default is enough digits to represent exactly the internal binary representation. Non-finite values are converted to `NA`, `NaN` or (perhaps a sign followed by) `Inf`. Format `%a` uses lower-case for `x`, `p` and the hex values; format `%A` uses upper-case.

  This should be supported on all platforms as it is a feature of C99. The format is not uniquely defined: although it would be possible to make the leading `h` always zero or one, this is not always done. Most systems will suppress trailing zeros, but a few do not. On a well-written platform, for normal numbers there will be a leading one before the decimal point plus (by default) 13 hexadecimal digits, hence 53 bits. The treatment of denormalized (aka ‘subnormal’) numbers is very platform-dependent.

- `s`: Character string. Character `NAs` are converted to "NA".

- `%`: Literal `%` (none of the extra formatting characters given below are permitted in this case).

Conversion by `as.character` is used for non-character arguments with `s` and by `as.double` for non-double arguments with `f`, `e`, `E`, `g`, `G`. NB: the length is determined before conversion, so do not rely on the internal coercion if this would change the length. The coercion is done only once, so if `length(fmt) > 1` then all elements must expect the same types of arguments.

In addition, between the initial `%` and the terminating conversion character there may be, in any order:

- `m.n`: Two numbers separated by a period, denoting the field width (`m`) and the precision (`n`).
- `-`: Left adjustment of converted argument in its field.
- `+`: Always print number with sign: by default only negative numbers are printed with a sign.
- `a`: Space prefix a space if the first character is not a sign.
- `0`: For numbers, pad to the field width with leading zeros. For characters, this zero-pads on some platforms and is ignored on others.
### sprintf

# specifies “alternate output” for numbers, its action depending on the type: For x or X, \$x or \$X
will be prefixed to a non-zero result. For e, E, f, g and G, the output will always have a decimal
point; for g and G, trailing zeros will not be removed.

Further, immediately after \% may come 1\$ to 99\$ to refer to a numbered argument: this allows
arguments to be referenced out of order and is mainly intended for translators of error messages. If
this is done it is best if all formats are numbered: if not the unnumbered ones process the arguments
in order. See the examples. This notation allows arguments to be used more than once, in which
case they must be used as the same type (integer, double or character).

A field width or precision (but not both) may be indicated by an asterisk *: in this case an argument
specifies the desired number. A negative field width is taken as a `-:' flag followed by a positive
field width. A negative precision is treated as if the precision were omitted. The argument should
be integer, but a double argument will be coerced to integer.

There is a limit of 8192 bytes on elements of fmt, and on strings included from a single \%letter
conversion specification.

Field widths and precisions of %s conversions are interpreted as bytes, not characters, as described
in the C standard.

The C doubles used for R numerical vectors have signed zeros, which sprintf may output as -0,
-0.000 . . .

#### Value

A character vector of length that of the longest input. If any element of fmt or any character
argument is declared as UTF-8, the element of the result will be in UTF-8 and have the encoding
declared as UTF-8. Otherwise it will be in the current locale’s encoding.

#### Warning

The format string is passed down the OS’s sprintf function, and incorrect formats can cause the
latter to crash the R process. R does perform sanity checks on the format, but not all possible user
errors on all platforms have been tested, and some might be terminal.

The behaviour on inputs not documented here is ‘undefined’, which means it is allowed to differ by
platform.

#### Author(s)

Original code by Jonathan Rougier.

`formatC` for a way of formatting vectors of numbers in a similar fashion.
`paste` for another way of creating a vector combining text and values.
`gettext` for the mechanisms for the automated translation of text.

Examples

```r
## be careful with the format: most things in R are floats
## only integer-valued reals get coerced to integer.

sprintf("%s is %f feet tall\n", "Sven", 7.1)  # OK
try(sprintf("%s is %i feet tall\n", "Sven", 7.1))  # not OK
  sprintf("%s is %i feet tall\n", "Sven", 7)  # OK

## use a literal %:

sprintf("%.0f%% said yes (out of a sample of size %.0f)", 66.666, 3)

## various formats of pi:

sprintf("%f", pi)
sprintf("%3f", pi)
sprintf("%1.0f", pi)
sprintf("%5.1f", pi)
sprintf("%05.1f", pi)
sprintf("%+f", pi)
sprintf("%-10f", pi)  # left justified
sprintf("%e", pi)
sprintf("%E", pi)
sprintf("%g", pi)
sprintf("%g", 1e6 * pi)  # => exponential
sprintf("%9g", 1e6 * pi)  # => "fixed"
sprintf("%G", 1e-6 * pi)

## no truncation:

sprintf("%1.f", 101)

## re-use one argument three times, show difference between %x and %X

xx <- sprintf("%1$d %1$x %1$X", 0:15)
xx <- matrix(xx, dimnames = list(rep("", 16), "%d%x%X"))
noquote(format(xx, justify = "right"))

## More sophisticated:

sprintf("min 10-char string '%%10s'",
  c("a", "ABC", "and an even longer one"))

## Platform-dependent bad example from qdapTools 1.0.0:
## may pad with spaces or zeroes.

sprintf("%09s", month.name)

n <- 1:18
sprintf(paste0("e with %2d digits = %.", n, "g"), n, exp(1))

## Using arguments out of order
```
sQuote("second $1.0f, first $5.2f, third $1.0f", pi, 2, 3)

## Using asterisk for width or precision
sprintf("%*.3f", 3, pi, 8, pi)

## Asterisk and argument re-use, 'e' example reiterated:
sprintf("e with %1$2d digits = %2$.1$g", n, exp(1))

## re-cycle arguments
sprintf("%s %d", "test", 1:3)

## binary output showing rounding/representation errors
x <- seq(0, 1.0, 0.1); y <- c(0,.1,.2,.3,.4,.5,.6,.7,.8,.9,1)
cbind(x, sprintf("%a", x), sprintf("%a", y))

-------

sQuote | Quote Text
--------|-----------------

Description

Single or double quote text by combining with appropriate single or double left and right quotation marks.

Usage

sQuote(x, q =getOption("useFancyQuotes"))
dQuote(x, q =getOption("useFancyQuotes"))

Arguments

x | an R object, to be coerced to a character vector.
q | the kind of quotes to be used, see ‘Details’.

Details

The purpose of the functions is to provide a simple means of markup for quoting text to be used in the R output, e.g., in warnings or error messages.

The choice of the appropriate quotation marks depends on both the locale and the available character sets. Older Unix/X11 fonts displayed the grave accent (ASCII code 0x60) and the apostrophe (0x27) in a way that they could also be used as matching open and close single quotation marks. Using modern fonts, or non-Unix systems, these characters no longer produce matching glyphs. Unicode provides left and right single quotation mark characters (U+2018 and U+2019); if Unicode markup cannot be assumed to be available, it seems good practice to use the apostrophe as a non-directional single quotation mark.

Similarly, Unicode has left and right double quotation mark characters (U+201C and U+201D); if only ASCII’s typewriter characteristics can be employed, than the ASCII quotation mark (0x22) should be used as both the left and right double quotation mark.

Some other locales also have the directional quotation marks, notably on Windows. TeX uses grave and apostrophe for the directional single quotation marks, and doubled grave and doubled apostrophe for the directional double quotation marks.
What rendering is used depends on `q` which by default depends on the `options` setting for `useFancyQuotes`. If this is `FALSE` then the undirectional ASCII quotation style is used. If this is `TRUE` (the default), Unicode directional quotes are used are used where available (currently, UTF-8 locales on Unix-alikes and all Windows locales except C): if set to "UTF-8" UTF-8 markup is used (whatever the current locale). If set to "TeX", TeX-style markup is used. Finally, if this is set to a character vector of length four, the first two entries are used for beginning and ending single quotes and the second two for beginning and ending double quotes: this can be used to implement non-English quoting conventions such as the use of guillemets.

Where fancy quotes are used, you should be aware that they may not be rendered correctly as not all fonts include the requisite glyphs: for example some have directional single quotes but not directional double quotes.

**Value**

A character vector of the same length as `x` (after any coercion) in the current locale’s encoding.

**References**

**See Also**

Quotes for quoting R code.

`shQuote` for quoting OS commands.

**Examples**

```r
op <- options("useFancyQuotes")
paste("argument", sQuote("x"), "must be non-zero")
options(useFancyQuotes = FALSE)
cat("\ndistinguish plain", sQuote("single"), "and",
    dQuote("double"), "quotes\n")
options(useFancyQuotes = TRUE)
cat("\ndistinguish fancy", sQuote("single"), "and",
    dQuote("double"), "quotes\n")
options(useFancyQuotes = "TeX")
cat("\ndistinguish TeX", sQuote("single"), "and",
    dQuote("double"), "quotes\n")
if(l10n_info()$"Latin-1") {
    options(useFancyQuotes = c("\xab", "\xbb", "\xbf", "?"))
cat("\n", sQuote("guillemet"), "and",
    dQuote("Spanish question"), "styles\n")
} else if(l10n_info()$"UTF-8") {
    options(useFancyQuotes = c("\xc2\xab", "\xc2\xbb", "\xc2\xbf", "?"))
cat("\n", sQuote("guillemet"), "and",
    dQuote("Spanish question"), "styles\n")
}
options(op)
```
srcfile References to Source Files and Code

Description

These functions are for working with source files and more generally with “source references” ("srcref"), i.e., references to source code. The resulting data is used for printing and source level debugging, and is typically available in interactive R sessions, namely when `options(keep.source = TRUE)`.

Usage

```r
srcfile(filename, encoding = getOption("encoding"), Enc = "unknown")
srcfilecopy(filename, lines, timestamp = Sys.time(), isFile = FALSE)
srcfilealias(filename, srcfile)
getSrcLines(srcfile, first, last)
srcref(srcfile, lloc)
## S3 method for class 'srcfile'
print(x, ...)
## S3 method for class 'srcfile'
summary(object, ...)
## S3 method for class 'srcfile'
open(con, line, ...)
## S3 method for class 'srcref'
close(con, ...)
## S3 method for class 'srcref'
print(x, useSource = TRUE, ...)
## S3 method for class 'srcref'
summary(object, useSource = FALSE, ...)
## S3 method for class 'srcref'
as.character(x, useSource = TRUE, to = x, ...)
.isOpen(srcfile)
```

Arguments

- `filename`: The name of a file.
- `encoding`: The character encoding to assume for the file.
- `Enc`: The encoding with which to make strings: see the encoding argument of `parse`.
- `lines`: A character vector of source lines. Other R objects will be coerced to character.
- `timestamp`: The timestamp to use on a copy of a file.
- `isFile`: Is this `srcfilecopy` known to come from a file system file?
- `srcfile`: A `srcfile` object.
- `first, last, line`: Line numbers.
- `lloc`: A vector of four, six or eight values giving a source location; see ‘Details’.
- `x, object, con`: An object of the appropriate class.
- `useSource`: Whether to read the `srcfile` to obtain the text of a `srcref`.
- `to`: An optional second `srcref` object to mark the end of the character range.
- `...`: Additional arguments to the methods; these will be ignored.
Details

These functions and classes handle source code references.

The srcfile function produces an object of class srcfile, which contains the name and directory of a source code file, along with its timestamp, for use in source level debugging (not yet implemented) and source echoing. The encoding of the file is saved; see file for a discussion of encodings, and iconvlist for a list of allowable encodings on your platform.

The srcfilecopy function produces an object of the descendant class srcfilecopy, which saves the source lines in a character vector. It copies the value of the isfile argument, to help debuggers identify whether this text comes from a real file in the file system.

The srcfilealias function produces an object of the descendant class srcfilealias, which gives an alternate name to another srcfile. This is produced by the parser when a #line directive is used.

The srcref function produces an object of class srcref, which describes a range of characters in a srcfile. The lloc value gives the following values:

\[\begin{align*}
\text{c(first_line, first_byte, last_line, last_byte, first_column, last_column, first_parsed, last_parsed)}
\end{align*}\]

Bytes (elements 2, 4) and columns (elements 5, 6) may be different due to multibyte characters. If only four values are given, the columns and bytes are assumed to match. Lines (elements 1, 3) and parsed lines (elements 7, 8) may differ if a #line directive is used in code: the former will respect the directive, the latter will just count lines. If only 4 or 6 elements are given, the parsed lines will be assumed to match the lines.

Methods are defined for print, summary, open, and close for classes srcfile and srcfilecopy. The open method opens its internal file connection at a particular line; if it was already open, it will be repositioned to that line.

Methods are defined for print, summary and as.character for class srcref. The as.character method will read the associated source file to obtain the text corresponding to the reference. If the to argument is given, it should be a second srcref that follows the first, in the same file; they will be treated as one reference to the whole range. The exact behaviour depends on the class of the source file. If the source file inherits from class srcfilecopy, the lines are taken from the saved copy using the “parsed” line counts. If not, an attempt is made to read the file, and the original line numbers of the srcref record (i.e., elements 1 and 3) are used. If an error occurs (e.g., the file no longer exists), text like <srcref: "file" chars 1:1 to 2:10> will be returned instead, indicating the line:column ranges of the first and last character. The summary method defaults to this type of display.

Lists of srcref objects may be attached to expressions as the "srcref" attribute. (The list of srcref objects should be the same length as the expression.) By default, expressions are printed by print.default using the associated srcref. To see deparsed code instead, call print with argument useSource = FALSE. If a srcref object is printed with useSource = FALSE, the <srcref: ...> record will be printed.

isOpen is intended for internal use: it checks whether the connection associated with a srcfile object is open.

Value

srcfile returns a srcfile object.
srcfilecopy returns a srcfilecopy object.
getSrcLines returns a character vector of source code lines.
srcref returns a srcref object.
standardGeneric

Author(s)
Duncan Murdoch

See Also
getSrcFilename for extracting information from a source reference, or removeSource to remove it from a (non-primitive) function (aka ‘closure’).

Examples

# has timestamp
src <- srcfile(system.file("DESCRIPTION", package = "base"))
summary(src)
getSrcLines(src, 1, 4)
ref <- srcref(src, c(1, 1, 2, 1000))
ref
print(ref, useSource = FALSE)

standardGeneric  Formal Method System – Dispatching S4 Methods

Description
The function standardGeneric initiates dispatch of S4 methods: see the references and the documentation of the methods package. Usually, calls to this function are generated automatically and not explicitly by the programmer.

Usage

standardGeneric(f, fdef)

Arguments

f The name of the generic.
fdef The generic function definition. Never passed when defining a new generic.

Details
standardGeneric dispatches the method defined for a generic function named f, using the actual arguments in the frame from which it is called.

The argument fdef is inserted (automatically) when dispatching methods for a primitive function. If present, it must always be the function definition for the corresponding generic. Don’t insert this argument by hand, as there is no validity checking and miss-specifying the function definition will cause certain failure.

For more, use the methods package, and see the documentation in GenericFunctions.

startsWith

Does String Start or End With Another String?

Description

Determines if entries of \( x \) start or end with string (entries of) \( \text{prefix} \) or \( \text{suffix} \) respectively, where strings are recycled to common lengths.

Usage

\[
\text{startsWith}(x, \text{prefix}) \\
\text{endsWith}(x, \text{suffix})
\]

Arguments

\( x \) vector of \text{character} string whose “starts” are considered.

\( \text{prefix}, \text{suffix} \) character vector (often of length one).

Details

\text{startsWith()} \text{ is equivalent to but much faster than}

\[
\text{substring}(x, 1, \text{nchar}(\text{prefix})) == \text{prefix}
\]

or also

\[
\text{grepl}("^<\text{prefix}>", x)
\]

where \( \text{prefix} \) is not to contain special regular expression characters (and for \text{grepl}, \( x \) does not contain missing values, see below).

The code has an optimized branch for the most common usage in which \( \text{prefix} \) or \( \text{suffix} \) is of length one, and is further optimized in a UTF-8 or 8-byte locale if that is an ASCII string.

Value

A \text{logical} vector, of “common length” of \( x \) and \( \text{prefix} \) (or \( \text{suffix} \)), i.e., of the longer of the two lengths unless one of them is zero when the result is also of zero length. A shorter input is recycled to the output length.

See Also

\text{grepl, substring}; the partial string matching functions \text{charmatch} \text{ and } \text{pmatch} solve a different task.
Examples

```r
startsWith(search(), "package:" ) # typically at least two FALSE, nowadays often three

x1 <- c("Foobar", "bla bla", "something", "another", "blu", "brown", "blau blüht der Enzian")# non-ASCII
x2 <- cbind(
  startsWith(x1, "b"),
  startsWith(x1, "bl"),
  startsWith(x1, "bla"),
  endsWith(x1, "n"),
  endsWith(x1, "an"))
rownames(x2) <- x1; colnames(x2) <- c("b", "bl", "bla", "n", "an")
x2

## Non-equivalence in case of missing values in 'x', see Details:
x <- c("all", "but", NA_character_)
cbind(startsWith(x, "a"),
      substring(x, 1L, 1L) == "a",
      grepl("^a", x))
```

Description

In R, the startup mechanism is as follows.

Unless '--no-environ' was given on the command line, R searches for site and user files to process for setting environment variables. The name of the site file is the one pointed to by the environment variable R_ENVIRON; if this is unset, 'R_HOME/etc/Renviron.site' is used (if it exists, which it does not in a 'factory-fresh' installation). The name of the user file can be specified by the R_ENVIRON_USER environment variable; if this is unset, the files searched for are '.Renviron' in the current or in the user's home directory (in that order). See 'Details' for how the files are read.

Then R searches for the site-wide startup profile file of R code unless the command line option '--no-site-file' was given. The path of this file is taken from the value of the R_PROFILE environment variable (after tilde expansion). If this variable is unset, the default is 'R_HOME/etc/Rprofile.site', which is used if it exists (which it does not in a 'factory-fresh' installation). This code is sourced into the base package. Users need to be careful not to unintentionally overwrite objects in base, and it is normally advisable to use local if code needs to be executed: see the examples.

Then, unless '--no-init-file' was given, R searches for a user profile, a file of R code. The path of this file is taken from the value of the R_PROFILE_USER environment variable (after tilde expansion). If this variable is unset, the default is 'R_HOME/etc/Rprofile.site', which is used if it exists (which it does not in a 'factory-fresh' installation). This code is sourced into the base package. Users need to be careful not to unintentionally overwrite objects in base, and it is normally advisable to use local if code needs to be executed: see the examples.

Note that when the site and user profile files are sourced only the base package is loaded, so objects in other packages need to be referred to by e.g. utils::dump.frames or after explicitly loading the package concerned.

R then loads a saved image of the user workspace from '.RData' in the current directory if there is one (unless '--norestore-data' or '--no-restore' was specified on the command line).

Next, if a function .First is found on the search path, it is executed as .First(). Finally, function .First.sys() in the base package is run. This calls require to attach the default packages
specified by `options("defaultPackages")`. If the `methods` package is included, this will have been attached earlier (by function `.OptRequireMethods()`) so that namespace initializations such as those from the user workspace will proceed correctly.

A function `.First` (and `.Last`) can be defined in appropriate `.Rprofile` or `.Rprofile.site` files or have been saved in `.RData`. If you want a different set of packages than the default ones when you start, insert a call to `options` in the `.Rprofile` or `.Rprofile.site` file. For example, `options(defaultPackages = character())` will attach no extra packages on startup (only the `base` package) (or set R_DEFAULT_PACKAGES=NULL as an environment variable before running R). Using `options(defaultPackages = "")` or R_DEFAULT_PACKAGES="" enforces the R system default.

On front-ends which support it, the commands history is read from the file specified by the environment variable `R_HISTFILE` (default `.Rhistory` in the current directory) unless `--no-restore-history` or `--no-restore` was specified.

The command-line option `--vanilla` implies `--no-site-file`, `--no-init-file`, `--no-environ` and (except for `R CMD`) `--no-restore`

Details

Note that there are two sorts of files used in startup: environment files which contain lists of environment variables to be set, and profile files which contain R code.

Lines in a site or user environment file should be either comment lines starting with #, or lines of the form `name=value`. The latter sets the environmental variable `name` to `value`, overriding an existing value. If `value` contains an expression of the form `$foo=bar`, the value is that of the environmental variable `foo` if that is set, otherwise `bar`. For `$foo:-bar`, the value is that of `foo` if that is set to a non-empty value, otherwise `bar`. (If it is of the form `$foo`, the default is ".") This construction can be nested, so `bar` can be of the same form (as in `$foo-$bar-blah`). Note that the braces are essential: for example `$HOME` will not be interpreted.

Leading and trailing white space in `value` are stripped. `value` is then processed in a similar way to a Unix shell: in particular the outermost level of (single or double) quotes is stripped, and backslashes are removed except inside quotes.

On systems with sub-architectures (mainly Windows), the files ‘Renviron.site’ and ‘Rprofile.site’ are looked for first in architecture-specific directories, e.g. `.R_HOME/etc/i386/Renviron.site`. And e.g. ‘.Renviron.i386’ will be used in preference to ‘.Renviron’.

Note

It is not intended that there be interaction with the user during startup code. Attempting to do so can crash the R process.

On Unix versions of R there is also a file ‘.R_HOME/etc/Renviron’ which is read very early in the start-up processing. It contains environment variables set by R in the configure process. Values in that file can be overridden in site or user environment files: do not change ‘.R_HOME/etc/Renviron’ itself. Note that this is distinct from ‘.R_HOME/etc/Renviron.site’.

Command-line options may well not apply to alternative front-ends: they do not apply to R.app on macOS.

R CMD check and R CMD build do not always read the standard startup files, but they do always read specific ‘Renviron’ files. The location of these can be controlled by the environment variables R_CHECK_ENVIRON and R_BUILD_ENVIRON. If these are set their value is used as the path for
the ‘Renviron’ file; otherwise, files ‘~/.R/check.Renviron’ or ‘~/.R/build.Renviron’ or subarchitecture-specific versions are employed.

If you want ‘~/.Renviron’ or ‘~/.Rprofile’ to be ignored by child R processes (such as those run by R CMD check and R CMD build), set the appropriate environment variable R_ENVIRON_USER or R_PROFILE_USER to (if possible, which it is not on Windows) "" or to the name of a non-existent file.

Prior to R 4.0.0, ${foo-bar} in an environment file skipped an empty foo: this has been changed to match the POSIX rules for parameter substitution in shells.

Examples

## Not run:
## Example ~/.Renviron on Unix
R_LIBS=~/.R/library
PAGER=~usr/local/bin/less

## Example .Renviron on Windows
R_LIBS=C:/R/library
MY_TCLTK="c:/Program Files/Tcl/bin"

## Example of setting R_DEFAULT_PACKAGES (from R CMD check)
R_DEFAULT_PACKAGES='utils,grDevices,graphics,stats'
# this loads the packages in the order given, so they appear on
# the search path in reverse order.

## Example of .Rprofile
options(width=65, digits=5)
options(show.signif.stars=FALSE)
setHook(packageEvent("grDevices", "onLoad"),
  function(...) grDevices::ps.options(horizontal=FALSE))
set.seed(1234)
.First <- function() cat("\n Welcome to R!\n\n")
.Last <- function() cat("\n Goodbye!\n\n")

## Example of Rprofile.site
local(
  # add MASS to the default packages, set a CRAN mirror
  old <- getOption("defaultPackages"); r <- getOption("repos")
  r["CRAN"] <- "http://my.local.cran"
  options(defaultPackages = c(old, "MASS"), repos = r)
## (for Unix terminal users) set the width from COLUMNS if set
cols <- Sys.getenv("COLUMNS")
if(nzchar(cols)) options(width = as.integer(cols))
# interactive sessions get a fortune cookie (needs fortunes package)
if (interactive())
  fortunes::fortune()
}

## if .Renviron contains
FOOBAR="coo\bar"doh\ex"abc"\def"

## then we get
# > cat(Sys.getenv("FOOBAR"), "\n")
# coo\bardoh\exabc\def'

## End(Not run)

---

**stop**

**Stop Function Execution**

### Description

`stop` stops execution of the current expression and executes an error action.

`geterrmessage` gives the last error message.

### Usage

```r
stop(..., call. = TRUE, domain = NULL)
geterrmessage()
```

### Arguments

- `...`: zero or more objects which can be coerced to character (and which are pasted together with no separator) or a single condition object.
- `call.`: logical, indicating if the call should become part of the error message.
- `domain`: see `gettext`. If NA, messages will not be translated.

### Details

The error action is controlled by error handlers established within the executing code and by the current default error handler set by `options(error=)`. The error is first signaled as if using `signalCondition()`. If there are no handlers or if all handlers return, then the error message is printed (if `options("show.error.messages")` is true) and the default error handler is used. The default behaviour (the NULL error-handler) in interactive use is to return to the top level prompt or the top level browser, and in non-interactive use to (effectively) call `q("no",status = 1,runLast = FALSE)`. The default handler stores the error message in a buffer; it can be retrieved by `geterrmessage()`. It also stores a trace of the call stack that can be retrieved by `traceback()`.

Errors will be truncated to `getOption("warning.length")` characters, default 1000.

If a condition object is supplied it should be the only argument, and further arguments will be ignored, with a warning.
Value

geterrmessage gives the last error message, as a character string ending in "\n".

Note

Use domain = NA whenever ... contain a result from gettext() as that is translated already.

References

See Also

warning, try to catch errors and retry, and options for setting error handlers. stopifnot for validity testing. tryCatch and withCallingHandlers can be used to establish custom handlers while executing an expression.

ggettext for the mechanisms for the automated translation of messages.

Examples

iter <- 12
try(if(iter > 10) stop("too many iterations"))

tst1 <- function(...) stop("dummy error")
try(tst1(1:10, long, calling, expression))

tst2 <- function(...) stop("dummy error", call. = FALSE)
try(tst2(1:10, longcalling, expression, but.not.seen.in.Error))
Note that e.g., positive numbers are not TRUE, even when they are coerced to TRUE, e.g., inside if(.) or in arithmetic computations in R.
If names are provided to . . ., they will be used in lieu of the default error message.

exprObject alternative to exprs or . . .: an 'expression-like' object, typically an expression, but also a call, a name, or atomic constant such as TRUE.

local (only when exprs is used:) indicates the environment in which the expressions should be evaluated; by default the one from where stopifnot() has been called.

Details
This function is intended for use in regression tests or also argument checking of functions, in particular to make them easier to read.

stopifnot(A,B) or equivalently stopifnot(exprs= {A ; B}) are conceptually equivalent to

\[
\begin{align*}
\{ & \text{if}(\text{any}(\text{is.na}(A)) \ || \ \text{!all}(A)) \ \text{stop}(\ldots); \\
& \text{if}(\text{any}(\text{is.na}(B)) \ || \ \text{!all}(B)) \ \text{stop}(\ldots) \} \\
\end{align*}
\]

Since R version 3.6.0, stopifnot() no longer handles potential errors or warnings (by tryCatch() etc) for each single expression and may use sys.call(<n>) to get a meaningful and short error message in case an expression did not evaluate to all TRUE. This provides considerably less overhead.

Since R version 3.5.0, expressions are evaluated sequentially, and hence evaluation stops as soon as there is a "non-TRUE", as indicated by the above conceptual equivalence statement.

Also, since R version 3.5.0, stopifnot(exprs = { . . . }) can be used alternatively and may be preferable in the case of several expressions, as they are more conveniently evaluated interactively ("no extraneous , ").

Since R version 3.4.0, when an expression (from . . .) is not true and is a call to all.equal, the error message will report the (first part of the) differences reported by all.equal(*).

Value
(NULL if all statements in . . . are TRUE.)

Note
Trying to use the stopifnot(exprs = . . .) version via a shortcut, say,

\[
\text{assertWRONG <- function(exprs) stopifnot(exprs = exprs)}
\]

is delicate and the above is not a good idea. Contrary to stopifnot() which takes care to evaluate the parts of exprs one by one and stop at the first non-TRUE, the above short cut would typically evaluate all parts of exprs and pass the result, i.e., typically of the last entry of exprs to stopifnot().

However, a more careful version,

\[
\text{assert <- function(exprs) eval.parent(substitute(stopifnot(exprs = exprs)))}
\]

may be a nice short cut for stopifnot(exprs = *) calls using the more commonly known verb as function name.
See Also

`stop`, `warning`; `assertCondition` in package `tools` complements `stopifnot()` for testing warnings and errors.

Examples

```r
stopifnot(1 == 1, all.equal(pi, 3.14159265), 1 < 2) # all TRUE

m <- matrix(c(1,3,3,1), 2, 2)
stopifnot(m == t(m), diag(m) == rep(1, 2)) # all(.) |=> TRUE

op <- options(error = expression(NULL))
# "disabling stop(.)"  << Use with CARE! >>

stopifnot(length(10)) # gives an error: '1' is *not* TRUE
## even when if(1) "ok" works

stopifnot(all.equal(pi, 3.141593), 2 < 2, (1:10 < 12), "a" < "b")
## More convenient for interactive "line by line" evaluation:
stopifnot(exprs = {
  all.equal(pi, 3.1415927)
  2 < 2
  1:10 < 12
  "a" < "b"
})

eObj <- expression(2 < 3, 3 <= 6, 1:10 < 2)
stopifnot(exprObject = eObj)
stopifnot(exprObject = quote(3 == 3))
stopifnot(exprObject = TRUE)

# long all.equal() error messages are abbreviated:
stopifnot(all.equal(rep(list(pi),4), list(3.1, 3.14, 3.141, 3.1415)))

# The default error message can be overridden to be more informative:
m[1,2] <- 12
stopifnot("m must be symmetric"= m == t(m))
#=> Error: m must be symmetric

options(op)  # revert to previous error handler
```

---

**strptime**

**Date-time Conversion Functions to and from Character**

**Description**

Functions to convert between character representations and objects of classes "POSIXlt" and "POSIXct" representing calendar dates and times.

**Usage**

```r
## S3 method for class 'POSIXct'
format(x, format = "", tz = ", usez = FALSE, 
```
## S3 method for class 'POSIXlt'
format(x, format = "", usetz = FALSE, ...)

## S3 method for class 'POSIXt'
as.character(x, ...)

strftime(x, format = "", tz = "", usetz = FALSE, ...)
strptime(x, format, tz = "")

Arguments

- **x**: An object to be converted: a character vector for `strptime`, an object which can be converted to "POSIXlt" for `strftime`.
- **tz**: A character string specifying the time zone to be used for the conversion. System-specific (see `as.POSIXlt`), but "" is the current time zone, and "GMT" is UTC. Invalid values are most commonly treated as UTC, on some platforms with a warning.
- **format**: A character string. The default for the format methods is "%Y-%m-%d %H:%M:%S" if any element has a time component which is not midnight, and "%Y-%m-%d" otherwise. If `options("digits.secs")` is set, up to the specified number of digits will be printed for seconds.
- **...**: Further arguments to be passed from or to other methods.
- **usetz**: logical. Should the time zone abbreviation be appended to the output? This is used in printing times, and more reliable than using "%Z".

Details

The `format` and `as.character` methods and `strftime` convert objects from the classes "POSIXlt" and "POSIXct" to character vectors.

`strptime` converts character vectors to class "POSIXlt": its input x is first converted by `as.character`. Each input string is processed as far as necessary for the format specified: any trailing characters are ignored.

`strftime` is a wrapper for `format.POSIXlt`, and it and `format.POSIXct` first convert to class "POSIXlt" by calling `as.POSIXlt` (so they also work for class "Date"). Note that only that conversion depends on the time zone.

The usual vector re-cycling rules are applied to x and format so the answer will be of length of the longer of these vectors.

Locale-specific conversions to and from character strings are used where appropriate and available. This affects the names of the days and months, the AM/PM indicator (if used) and the separators in output formats such as %x and %X, via the setting of the `LC_TIME` locale category. The 'current locale' of the descriptions might mean the locale in use at the start of the R session or when these functions are first used. (For input, the locale-specific conversions can be changed by calling `Sys.setlocale` with category `LC_TIME` (or `LC_ALL`). For output, what happens depends on the OS but usually works.)

The details of the formats are platform-specific, but the following are likely to be widely available: most are defined by the POSIX standard. A conversion specification is introduced by %, usually followed by a single letter or 0 or E and then a single letter. Any character in the format string not part of a conversion specification is interpreted literally (and %% gives %). Widely implemented conversion specifications include
%a Abbreviated weekday name in the current locale on this platform. (Also matches full name on input: in some locales there are no abbreviations of names.)

%A Full weekday name in the current locale. (Also matches abbreviated name on input.)

%b Abbreviated month name in the current locale on this platform. (Also matches full name on input: in some locales there are no abbreviations of names.)

%B Full month name in the current locale. (Also matches abbreviated name on input.)

%c Date and time. Locale-specific on output, "%a %b %e %H:%M:%S %Y" on input.

%C Century (00–99): the integer part of the year divided by 100.

%d Day of the month as decimal number (01–31).

%d Date format such as %m/%d/%Y: the C99 standard says it should be that exact format (but not all OSes comply).

%e Day of the month as decimal number (01–31), with a leading space for a single-digit number.

%E Equivalent to %Y-%m-%d (the ISO 8601 date format).

%g The last two digits of the week-based year (see %V). (Accepted but ignored on input.)

%G The week-based year (see %V) as a decimal number. (Accepted but ignored on input.)

%h Equivalent to %b.

%H Hours as decimal number (00–23). As a special exception strings such as '24:00:00' are accepted for input, since ISO 8601 allows these.

%I Hours as decimal number (01–12).

%j Day of year as decimal number (001–366): For input, 366 is only valid in a leap year.

%m Month as decimal number (01–12).

%m Minute as decimal number (00–59).

%n Newline on output, arbitrary whitespace on input.

%p AM/PM indicator in the locale. Used in conjunction with %I and not with %H. An empty string in some locales (for example on some OSes, non-English European locales including Russia). The behaviour is undefined if used for input in such a locale.

Some platforms accept %P for output, which uses a lower-case version (%p may also use lower case): others will output P.

%r For output, the 12-hour clock time (using the locale’s AM or PM): only defined in some locales, and on some OSes misleading in locales which do not define an AM/PM indicator. For input, equivalent to %I:%M:%S %p.

%R Equivalent to %H:%M.

%S Second as integer (00–61), allowing for up to two leap-seconds (but POSIX-compliant implementations will ignore leap seconds).

%t Tab on output, arbitrary whitespace on input.

%T Equivalent to %H:%M:%S.

%u Weekday as a decimal number (1–7, Monday is 1).

%U Week of the year as decimal number (00–53) using Sunday as the first day 1 of the week (and typically with the first Sunday of the year as day 1 of week 1). The US convention.

%V Week of the year as decimal number (01–53) as defined in ISO 8601. If the week (starting on Monday) containing 1 January has four or more days in the new year, then it is considered week 1. Otherwise, it is the last week of the previous year, and the next week is week 1. (Accepted but ignored on input.)

%W Weekday as decimal number (0–6, Sunday is 0).
%W Week of the year as decimal number (00–53) using Monday as the first day of week (and typically with the first Monday of the year as day 1 of week 1). The UK convention.

%x Date. Locale-specific on output, "%y/%m/%d" on input.

%X Time. Locale-specific on output, "%H:%M:%S" on input.

%y Year without century (00–99). On input, values 00 to 68 are prefixed by 20 and 69 to 99 by 19 – that is the behaviour specified by the 2018 POSIX standard, but it does also say `it is expected that in a future version the default century inferred from a 2-digit year will change`.

%Y Year with century. Note that whereas there was no zero in the original Gregorian calendar, ISO 8601:2004 defines it to be valid (interpreted as 1BC): see [https://en.wikipedia.org/wiki/0_(year)](https://en.wikipedia.org/wiki/0_(year)). However, the standards also say that years before 1582 in its calendar should only be used with agreement of the parties involved. For input, only years 0:9999 are accepted.

%z Signed offset in hours and minutes from UTC, so -0800 is 8 hours behind UTC. Values up to +1400 are accepted. (Standard only for output. For input R currently supports it on all platforms.)

%Z (Output only.) Time zone abbreviation as a character string (empty if not available). This may not be reliable when a time zone has changed abbreviations over the years.

Where leading zeros are shown they will be used on output but are optional on input. Names are matched case-insensitively on input: whether they are capitalized on output depends on the platform and the locale. Note that abbreviated names are platform-specific (although the standards specify that in the ‘C’ locale they must be the first three letters of the capitalized English name: this convention is widely used in English-language locales but for example the French month abbreviations are not the same on any two of Linux, macOS, Solaris and Windows). Knowing what the abbreviations are is essential if you wish to use %a, %b or %h as part of an input format: see the examples for how to check.

When %z or %Z is used for output with an object with an assigned time zone an attempt is made to use the values for that time zone — but it is not guaranteed to succeed.

Not in the standards and less widely implemented are

%k The 24-hour clock time with single digits preceded by a blank.

%l The 12-hour clock time with single digits preceded by a blank.

%S (Output only.) The number of seconds since the epoch.

%+ (Output only.) Similar to %c, often "%a %b %e %H:%M:%S %Z %Y". May depend on the locale.

For output there are also %O[%d%H%M%UVwWy] which may emit numbers in an alternative locale-dependent format (e.g., roman numerals), and %E[cCyYxx] which can use an alternative ‘era’ (e.g., a different religious calendar). Which of these are supported is OS-dependent. These are accepted for input, but with the standard interpretation.

Specific to R is %OSn, which for output gives the seconds truncated to $0 \leq n \leq 6$ decimal places (and if %OS is not followed by a digit, it uses the setting of `getOption("digits.secs")`, or if that is unset, $n = 0$). Further, for `strptime` %OS will input seconds including fractional seconds. Note that %S does not read fractional parts on output.

The behaviour of other conversion specifications (and even if other character sequences commencing with % are conversion specifications) is system-specific. Some systems document that the use of multi-byte characters in `format` is unsupported: UTF-8 locales are unlikely to cause a problem.
Value

The `format` methods and `strptime` return character vectors representing the time. NA times are returned as NA_character_. The elements are restricted to 256 bytes, plus a time zone abbreviation if `usetz` is true. (On known platforms longer strings are truncated at 255 or 256 bytes, but this is not guaranteed by the C99 standard.)

`strptime` turns character representations into an object of class "POSIXlt". The time zone is used to set the `isdst` component and to set the "tzone" attribute if `tz != ""`. If the specified time is invalid (for example "2010-02-30 08:00") all the components of the result are NA. (NB: this does means exactly what it says – if it is an invalid time, not just a time that does not exist in some time zone.)

Printing years

Everyone agrees that years from 1000 to 9999 should be printed with 4 digits, but the standards do not define what is to be done outside that range. For years 0 to 999 most OSes pad with zeros or spaces to 4 characters, and Linux outputs just the number.

OS facilities will probably not print years before 1 CE (aka 1 AD) ‘correctly’ (they tend to assume the existence of a year 0: see https://en.wikipedia.org/wiki/0_(year), and some OSes get them completely wrong). Common formats are -45 and -045.

Years after 9999 and before -999 are normally printed with five or more characters.

Some platforms support modifiers from POSIX 2008 (and others). On Linux the format "%04Y" assures a minimum of four characters and zero-padding. The internal code (as used on Windows and by default on macOS) uses zero-padding by default, and formats `% _4Y` and `% _Y` can be used for space padding and no padding.

Time zone offsets

Offsets from GMT (also known as UTC) are part of the conversion between timezones and to/from class "POSIXct", but cause difficulties as they are often computed incorrectly.

They conventionally have the opposite sign from time-zone specifications (see `Sys.timezone`): positive values are East of the meridian. Although there have been time zones with offsets like 00:09:21 (Paris in 1900), and 00:44:30 (Liberia until 1972), offsets are usually treated as whole numbers of minutes, and are most often seen in RFC 5322 email headers in forms like -0800 (e.g., used on the Pacific coast of the USA in winter).

Format `%z` can be used for input or output: it is a character string, conventionally plus or minus followed by two digits for hours and two for minutes: the standards say that an empty string should be output if the offset is unknown, but some systems use the offsets for the time zone in use for the current year.

Sources

Input uses the POSIX function `strptime` and output the C99 function `strftime`.

However, not all OSes (notably Windows) provided `strptime` and many issues were found for those which did, so since 2000 R has used a fork of code from ‘glibc’. The forked code uses the system’s `strptime` to find the locale-specific day and month names and any AM/PM indicator.

On some platforms (including Windows and by default on macOS) the system’s `strptime` is replaced (along with most of the rest of the C-level datetime code) by code modified from IANA’s ‘tzcode’ distribution (https://www.iana.org/time-zones).
Note

The default formats follow the rules of the ISO 8601 international standard which expresses a day as "2001-02-28" and a time as "14:01:02" using leading zeroes as here. (The ISO form uses no space to separate dates and times: R does by default.)

For `strptime` the input string need not specify the date completely: it is assumed that unspecified seconds, minutes or hours are zero, and an unspecified year, month or day is the current one. (However, if a month is specified, the day of that month has to be specified by `%d` or `%e` since the current day of the month need not be valid for the specified month.) Some components may be returned as `NA` (but an unknown `tzone` component is represented by an empty string).

If the time zone specified is invalid on your system, what happens is system-specific but it will probably be ignored.

Remember that in most time zones some times do not occur and some occur twice because of transitions to/from ‘daylight saving’ (also known as ‘summer’) time. `strptime` does not validate such times (it does not assume a specific time zone), but conversion by `as.POSIXct` will do so. Conversion by `strptime` and formatting/printing uses OS facilities and may return nonsensical results for non-existent times at DST transitions.

In a C locale `%c` is required to be "%a %b %e %H:%M:%S %Y". As Windows does not comply (and uses a date format not understood outside N. America), that format is used by R on Windows in all locales.

References

The POSIX 1003.1 standard, which is in some respects stricter than ISO 8601.

See Also

`DateTimeClasses` for details of the date-time classes; `locales` to query or set a locale.

Your system’s help page on `strptime` to see how to specify their formats. (On some systems, including Windows, `strptime` is replaced by more comprehensive internal code.)

Examples

```r
## locale-specific version of date()
format(Sys.time(), "%a %b %d %X %Y %Z")

## time to sub-second accuracy (if supported by the OS)
format(Sys.time(), "%H:%M:%OS3")

## read in date info in format 'dmmmyyyy'
## This will give NA(s) in some non-English locales; setting the C locale
## as in the commented lines will overcome this on most systems.
## lct <- Sys.getlocale("LC_TIME"); Sys.setlocale("LC_TIME", "C")
x <- c("1jan1960", "2jan1960", "31mar1960", "30jul1960")
z <- strftime(x, "%d%m%Y")
## Sys.setlocale("LC_TIME", lct)
```
z

## read in date/time info in format 'm/d/y h:m:s'
dates <- c("02/27/92", "02/27/92", "01/14/92", "02/28/92", "02/01/92")
x <- paste(dates, times)
strptime(x, "%m/%d/%y %H:%M:%S")

## time with fractional seconds
z <- strptime("20/2/06 11:16:16.683", "%d/%m/%y %H:%M:%OS")

## prints without fractional seconds
op <- options(digits.secs = 3)
z
options(op)

## time zone names are not portable, but 'EST5EDT' comes pretty close.
(x <- strptime(c("2006-01-08 10:07:52", "2006-08-07 19:33:02"),
   "%Y-%m-%d %H:%M:%S", tz = "EST5EDT"))
attr(x, "tzone")

## An RFC 5322 header (Eastern Canada, during DST)
## In a non-English locale the commented lines may be needed.
## prev <- Sys.getlocale("LC_TIME"); Sys.setlocale("LC_TIME", "C")
strptime("Tue, 23 Mar 2010 14:36:38 -0400", "%a, %d %b %Y %H:%M:%S %z")
## Sys.setlocale("LC_TIME", prev)

## Make sure you know what the abbreviated names are for you if you wish
## to use them for input (they are matched case-insensitively):
format(seq.Date(as.Date("1978-01-01"), by = "day", len = 7), "%a")
format(seq.Date(as.Date("2000-01-01"), by = "month", len = 12), "%b")

---

**strrep**

**Repeat the Elements of a Character Vector**

**Description**

Repeat the character strings in a character vector a given number of times (i.e., concatenate the respective numbers of copies of the strings).

**Usage**

```
strrep(x, times)
```

**Arguments**

- `x` a character vector, or an object which can be coerced to a character vector using `as.character`.
- `times` an integer vector giving the (non-negative) numbers of times to repeat the respective elements of `x`.

**Details**

The elements of `x` and `times` will be recycled as necessary (if one has no elements, and empty character vector is returned). Missing elements in `x` or `times` result in missing elements of the return value.
Value

A character vector with the elements of the given character vector repeated the given numbers of times.

Examples

strrep("ABC", 2)
strrep(c("A", "B", "C"), 1 : 3)

## Create vectors with the given numbers of spaces:
strrep(" ", 1 : 5)

--

strsplit

Split the Elements of a Character Vector

Description

Split the elements of a character vector into substrings according to the matches to substring split within them.

Usage

strsplit(x, split, fixed = FALSE, perl = FALSE, useBytes = FALSE)

Arguments

x character vector, each element of which is to be split. Other inputs, including a factor, will give an error.

split character vector (or object which can be coerced to such) containing regular expression(s) (unless fixed = TRUE) to use for splitting. If empty matches occur, in particular if split has length 0, x is split into single characters. If split has length greater than 1, it is re-cycled along x.

fixed logical. If TRUE match split exactly, otherwise use regular expressions. Has priority over perl.

perl logical. Should Perl-compatible regexps be used?

useBytes logical. If TRUE the matching is done byte-by-byte rather than character-by-character, and inputs with marked encodings are not converted. This is forced (with a warning) if any input is found which is marked as "bytes" (see Encoding).

Details

Argument split will be coerced to character, so you will see uses with split = NULL to mean split = character(0), including in the examples below.

Note that splitting into single characters can be done via split = character(0) or split = ""; the two are equivalent. The definition of 'character' here depends on the locale: in a single-byte locale it is a byte, and in a multi-byte locale it is the unit represented by a 'wide character' (almost always a Unicode code point).

A missing value of split does not split the corresponding element(s) of x at all.

The algorithm applied to each input string is
repeat {
  if the string is empty
    break.
  if there is a match
    add the string to the left of the match to the output.
    remove the match and all to the left of it.
  else
    add the string to the output.
    break.
}

Note that this means that if there is a match at the beginning of a (non-empty) string, the first element of the output is "", but if there is a match at the end of the string, the output is the same as with the match removed.

Invalid inputs in the current locale are warned about up to 5 times.

Value
A list of the same length as x, the i-th element of which contains the vector of splits of x[i].

If any element of x or split is declared to be in UTF-8 (see Encoding), all non-ASCII character strings in the result will be in UTF-8 and have their encoding declared as UTF-8. For perl = TRUE, useBytes = FALSE all non-ASCII strings in a multibyte locale are translated to UTF-8.

See Also
paste for the reverse, grep and sub for string search and manipulation; also nchar, substr.
'regular expression' for the details of the pattern specification.

Option PCRE_use_JIT controls the details when perl = TRUE.

Examples
noquote(strsplit("A text I want to display with spaces", NULL)[[1]])

x <- c(as = "asfef", qu = "qwerty", "yuiop", "b", "stuff.blah.yech")
# split x on the letter e
strsplit(x, "e")

unlist(strsplit("a.b.c", "."))
## [1] "a" "b" "c"
## or
unlist(strsplit("a.b.c", ".", fixed = TRUE))

## a useful function: rev() for strings
strReverse <- function(x)
  sapply(lapply(strsplit(x, NULL), rev), paste, collapse = "")
strReverse(c("abc", "Statistics"))

## get the first names of the members of R-core
a <- readLines(file.path(R.home("doc"), "AUTHORS"))[-(1:8)]
a <- a[(0:2)-length(a)]
strtoi

Convert Strings to Integers

Description

Convert strings to integers according to the given base using the C function `strtol`, or choose a suitable base following the C rules.

Usage

```r
strtoi(x, base = 0L)
```

Arguments

- `x` a character vector, or something coercible to this by `as.character`.
- `base` an integer which is between 2 and 36 inclusive, or zero (default).

Details

Conversion is based on the C library function `strtol`.

For the default `base = 0L`, the base chosen from the string representation of that element of `x`, so different elements can have different bases (see the first example). The standard C rules for choosing the base are that octal constants (prefix `0` not followed by `x` or `X`) and hexadecimal constants (prefix `0x` or `0X`) are interpreted as base 8 and 16; all other strings are interpreted as base 10.

For a base greater than 10, letters a to z (or A to Z) are used to represent 10 to 35.

Value

An integer vector of the same length as `x`. Values which cannot be interpreted as integers or would overflow are returned as `NA_integer_`.

See Also

For decimal strings `as.integer` is equally useful.

Examples

```r
strtoi(c("0xff", "077", "123"))
strtoi(c("ffff", "FFFF"), 16L)
strtoi(c("177", "377"), 8L)
```
**strtrim**  
*Trim Character Strings to Specified Display Widths*

**Description**  
Trim character strings to specified display widths.

**Usage**  
`strtrim(x, width)`

**Arguments**  
- `x`  
a character vector, or an object which can be coerced to a character vector by `as.character`.  
- `width`  
Positive integer values: recycled to the length of `x`.

**Details**  
‘Width’ is interpreted as the display width in a monospaced font. What happens with non-printable characters (such as backspace, tab) is implementation-dependent and may depend on the locale (e.g., they may be included in the count or they may be omitted).  
Using this function rather than `substr` is important when there might be double-width (e.g., Chinese/Japanese/Korean) characters in the character vector.

**Value**  
A character vector of the same length and with the same attributes as `x` (after possible coercion).  
Elements of the result will have the encoding declared as that of the current locale (see Encoding) if the corresponding input had a declared encoding and the current locale is either Latin-1 or UTF-8.

**Examples**  
`strtrim(c("abcdef", "abcdef", "abcdef"), c(1,5,10))`

---

**structure**  
*Attribute Specification*

**Description**  
`structure` returns the given object with further attributes set.

**Usage**  
`structure(.Data, ...)`

**Arguments**  
- `.Data`  
an object which will have various attributes attached to it.  
- `...`  
attributes, specified in `tag = value` form, which will be attached to data.
Adding a class "factor" will ensure that numeric codes are given integer storage mode.

For historical reasons (these names are used when deparsing), attributes ".Dim", ".Dimnames", ".Names", ".Tsp" and ".Label" are renamed to "dim", "dimnames", "names", "tsp" and "levels".

It is possible to give the same tag more than once, in which case the last value assigned wins. As with other ways of assigning attributes, using tag = NULL removes attribute tag from .Data if it is present.

References

See Also

attributes, attr.

Examples

structure(1:6, dim = 2:3)

strwrap(x, width = 0.9 * getOption("width"), indent = 0,
    exdent = 0, prefix = "", simplify = TRUE, initial = prefix)

Arguments

x  a character vector, or an object which can be converted to a character vector by
    as.character.
width  a positive integer giving the target column for wrapping lines in the output.
indent  a non-negative integer giving the indentation of the first line in a paragraph.
exdent  a non-negative integer specifying the indentation of subsequent lines in paragraphs.
prefix, initial  a character string to be used as prefix for each line except the first, for which initial is used.
simplify  a logical. If TRUE, the result is a single character vector of line text; otherwise, it is a list of the same length as x the elements of which are character vectors of line text obtained from the corresponding element of x. (Hence, the result in the former case is obtained by unlisting that of the latter.)
### subset

**Description**

Return subsets of vectors, matrices or data frames which meet conditions.

**Usage**

```r
details <- subset(x, ...)  
## Default S3 method:  
details(x, subset, ...)  
## S3 method for class 'matrix'  
details(x, subset, select, drop = FALSE, ...)  
## S3 method for class 'data.frame'  
details(x, subset, select, drop = FALSE, ...)
```

### Value

A character vector (if `simplify` is `TRUE`), or a list of such character vectors, with declared input encodings preserved.

### Examples

```r
## Read in file 'THANKS'.
x <- paste(readLines(file.path(R.home("doc"), "THANKS")), collapse = "\n")
## Split into paragraphs and remove the first three ones
x <- unlist(strsplit(x, "\n\[ \t\n\]*\n\n\"][-c(1:3)])
## Join the rest
x <- paste(x, collapse = "\n\n")
## Now for some fun:
writeLines(strwrap(x, width = 60))
writeLines(strwrap(x, width = 60, indent = 5))
writeLines(strwrap(x, width = 60, exdent = 5))
writeLines(strwrap(x, prefix = "THANKS> "))

## Note that messages are wrapped AT the target column indicated by  
## 'width' (and not beyond it).
## From an R-devel posting by J. Hosking <jh910@juno.com>.
x <- paste(sapply(sample(10, 100, replace = TRUE),  
function(x) substring("aaaaaaaaaa", 1, x)), collapse = " ")
sapply(10:40,  
function(m)  
c(target = m, actual = max(nchar(strwrap(x, m)))))
```

### Details

Whitespace (space, tab or newline characters) in the input is destroyed. Double spaces after periods, question and explanation marks (thought as representing sentence ends) are preserved. Currently, possible sentence ends at line breaks are not considered specially.

Indentation is relative to the number of characters in the prefix string.
Arguments

- **x**: object to be subsettred.
- **subset**: logical expression indicating elements or rows to keep: missing values are taken as false.
- **select**: expression, indicating columns to select from a data frame.
- **drop**: passed on to `[` indexing operator.
- **...**: further arguments to be passed to or from other methods.

Details

This is a generic function, with methods supplied for matrices, data frames and vectors (including lists). Packages and users can add further methods.

For ordinary vectors, the result is simply `x[subset & !is.na(subset)]`.

For data frames, the `subset` argument works on the rows. Note that `subset` will be evaluated in the data frame, so columns can be referred to (by name) as variables in the expression (see the examples).

The `select` argument exists only for the methods for data frames and matrices. It works by first replacing column names in the selection expression with the corresponding column numbers in the data frame and then using the resulting integer vector to index the columns. This allows the use of the standard indexing conventions so that for example ranges of columns can be specified easily, or single columns can be dropped (see the examples).

The `drop` argument is passed on to the indexing method for matrices and data frames: note that the default for matrices is different from that for indexing.

Factors may have empty levels after subsetting; unused levels are not automatically removed. See `droplevels` for a way to drop all unused levels from a data frame.

Value

An object similar to `x` contain just the selected elements (for a vector), rows and columns (for a matrix or data frame), and so on.

Warning

This is a convenience function intended for use interactively. For programming it is better to use the standard subsetting functions like `[`, and in particular the non-standard evaluation of argument `subset` can have unanticipated consequences.

Examples

subset(airquality, Temp > 80, select = c(Ozone, Temp))
subset(airquality, Day == 1, select = -Temp)
subset(airquality, select = Ozone:Wind)

with(airquality, subset(Ozone, Temp > 80))

### sometimes requiring a logical 'subset' argument is a nuisance
nm <- rownames(state.x77)
start_with_M <- nm %in% grep("^M", nm, value = TRUE)
subset(state.x77, start_with_M, Illiteracy:Murder)
# but in recent versions of R this can simply be
subset(state.x77, grepl("^M", nm), Illiteracy:Murder)

substitute

Substituting and Quoting Expressions

Description

substitute returns the parse tree for the (unevaluated) expression expr, substituting any variables bound in env.

quote simply returns its argument. The argument is not evaluated and can be any R expression.

enquote is a simple one-line utility which transforms a call of the form Foo(....) into the call quote(Foo(....)). This is typically used to protect a call from early evaluation.

Usage

substitute(expr, env)
quote(expr)
enquote(cl)

Arguments

expr any syntactically valid R expression
cl a call, i.e., an R object of class (and mode) "call".
env an environment or a list object. Defaults to the current evaluation environment.

Details

The typical use of substitute is to create informative labels for data sets and plots. The myplot example below shows a simple use of this facility. It uses the functions deparse and substitute to create labels for a plot which are character string versions of the actual arguments to the function myplot.

Substitution takes place by examining each component of the parse tree as follows: If it is not a bound symbol in env, it is unchanged. If it is a promise object, i.e., a formal argument to a function or explicitly created using delayedAssign(), the expression slot of the promise replaces the symbol. If it is an ordinary variable, its value is substituted, unless env is .GlobalEnv in which case the symbol is left unchanged.

Both quote and substitute are 'special' primitive functions which do not evaluate their arguments.
**Value**

The mode of the result is generally "call" but may in principle be any type. In particular, single-variable expressions have mode "name" and constants have the appropriate base mode.

**Note**

substitute works on a purely lexical basis. There is no guarantee that the resulting expression makes any sense.

Substituting and quoting often cause confusion when the argument is `expression(...)`. The result is a call to the `expression` constructor function and needs to be evaluated with `eval` to give the actual expression object.

**References**

**See Also**

`missing` for argument 'missingness', `bquote` for partial substitution, `sQuote` and `dQuote` for adding quotation marks to strings, `all.names` to retrieve the symbol names from an expression or call.

**Examples**

```r
require(graphics)
(s.e <- substitute(expression(a + b), list(a = 1))) #> expression(1 + b)
(s.s <- substitute( a + b, list(a = 1))) #> 1 + b
c(mode(s.e), typeof(s.e)) # "call", "language"
c(mode(s.s), typeof(s.s)) # (the same)
# but:
(e.s.e <- eval(s.e)) #> expression(1 + b)
c(mode(e.s.e), typeof(e.s.e)) # "expression", "expression"
substitute(x <- x + 1, list(x = 1)) # nonsense

myplot <- function(x, y)
  plot(x, y, xlab = deparse1(substitute(x)),
       ylab = deparse1(substitute(y)))

## Simple examples about lazy evaluation, etc:

f1 <- function(x, y = x) { x <- x + 1; y }
s1 <- function(x, y = substitute(x)) { x <- x + 1; y }
s2 <- function(x, y) { if(missing(y)) y <- substitute(x); x <- x + 1; y }
a <- 10
f1(a) # 11
s1(a) # 11
s2(a) # a
typeof(s2(a)) # "symbol"
```
### Description

Extract or replace substrings in a character vector.

### Usage

- `substr(x, start, stop)`
- `substring(text, first, last = 1000000L)`
- `substr(x, start, stop) <- value`
- `substring(text, first, last = 1000000L) <- value`

### Arguments

- **x, text**: a character vector.
- **start, first**: integer. The first element to be replaced.
- **stop, last**: integer. The last element to be replaced.
- **value**: a character vector, recycled if necessary.

### Details

- `substring` is compatible with S, with `first` and `last` instead of `start` and `stop`. For vector arguments, it expands the arguments cyclically to the length of the longest provided none are of zero length.
- When extracting, if `start` is larger than the string length then "" is returned.
- For the extraction functions, `x` or `text` will be converted to a character vector by `as.character` if it is not already one.
- For the replacement functions, if `start` is larger than the string length then no replacement is done.
- If the portion to be replaced is longer than the replacement string, then only the portion the length of the string is replaced.
- If any argument is an NA element, the corresponding element of the answer is NA.
- Elements of the result will be have the encoding declared as that of the current locale (see Encoding) if the corresponding input had a declared Latin-1 or UTF-8 encoding and the current locale is either Latin-1 or UTF-8.
- If an input element has declared "bytes" encoding (see Encoding), the subsetting is done in units of bytes not characters.

### Value

- For `substr`, a character vector of the same length and with the same attributes as `x` (after possible coercion).
- For `substring`, a character vector of length the longest of the arguments. This will have names taken from `x` (if it has any after coercion, repeated as needed), and other attributes copied from `x` if it is the longest of the arguments).
- Elements of `x` with a declared encoding (see Encoding) will be returned with the same encoding.
Note

The S4 version of `substring` ignores `last`; this version does not.

These functions are often used with `nchar` to truncate a display. That does not really work (you want to limit the width, not the number of characters, so it would be better to use `strtrim`), but at least make sure you use the default `nchar(type = "c")`.

References

See Also

`strsplit`, `paste`, `nchar`.

Examples

```r
substr("abcdef", 2, 4)
substring("abcdef", 1:6, 1:6)
## strsplit is more efficient ...
substr(rep("abcdef", 4), 1:4, 4:5)
x <- c("asfef", "qwerty", "yuiop", "b", "stuff.blah.yech")
substr(x, 2, 5)
substring(x, 2:4:6)

substring(x, 2) <- c("..", "+++")
x
```

---

**sum**  
*Sum of Vector Elements*

Description

`sum` returns the sum of all the values present in its arguments.

Usage

```r
sum(..., na.rm = FALSE)
```

Arguments

- `...` numeric or complex or logical vectors.
- `na.rm` logical. Should missing values (including NaN) be removed?
Details

This is a generic function: methods can be defined for it directly or via the Summary group generic. For this to work properly, the arguments should be unnamed, and dispatch is on the first argument.

If na.rm is FALSE an NA or NaN value in any of the arguments will cause a value of NA or NaN to be returned, otherwise NA and NaN values are ignored.

Logical true values are regarded as one, false values as zero. For historical reasons, NULL is accepted and treated as if it were integer(0).

Loss of accuracy can occur when summing values of different signs: this can even occur for sufficiently long integer inputs if the partial sums would cause integer overflow. Where possible extended-precision accumulators are used, typically well supported with C99 and newer, but possibly platform-dependent.

Value

The sum. If all of the arguments are of type integer or logical, then the sum is integer when possible and is double otherwise. Integer overflow should no longer happen since R version 3.5.0. For other argument types it is a length-one numeric (double) or complex vector.

NB: the sum of an empty set is zero, by definition.

S4 methods

This is part of the S4 Summary group generic. Methods for it must use the signature x, . . . , na.rm.

'plotmath' for the use of sum in plot annotation.

References

See Also

colSums for row and column sums.

Examples

## Pass a vector to sum, and it will add the elements together.
sum(1:5)

## Pass several numbers to sum, and it also adds the elements.
sum(1, 2, 3, 4, 5)

## In fact, you can pass vectors into several arguments, and everything gets added.
sum(1:2, 3:5)

## If there are missing values, the sum is unknown, i.e., also missing, ....
sum(1:5, NA)

## ... unless we exclude missing values explicitly:
sum(1:5, NA, na.rm = TRUE)
**summary**

**Object Summaries**

**Description**

`summary` is a generic function used to produce result summaries of the results of various model fitting functions. The function invokes particular methods which depend on the class of the first argument.

**Usage**

```r
summary(object, ...)  
## Default S3 method:   
summary(object, ..., digits, quantile.type = 7)  
## S3 method for class 'data.frame'   
summary(object, maxsum = 7,   
         digits = max(3, getOption("digits")-3), ...)  
## S3 method for class 'factor'   
summary(object, maxsum = 100, ...)  
## S3 method for class 'matrix'   
summary(object, ...)  
## S3 method for class 'summaryDefault'   
format(x, digits = max(3L, getOption("digits") - 3L), ...)  
## S3 method for class 'summaryDefault'   
print(x, digits = max(3L, getOption("digits") - 3L), ...)```

**Arguments**

- `object` an object for which a summary is desired.
- `x` a result of the default method of `summary()`.
- `maxsum` integer, indicating how many levels should be shown for factors.
- `digits` integer, used for number formatting with `signif()` (for `summary.default`) or `format()` (for `summary.data.frame`). In `summary.default`, if not specified (i.e., `missing()`), `signif()` will not be called anymore (since R >= 3.4.0, where the default has been changed to only round in the print and format methods).
- `quantile.type` integer code used in `quantile(*,type=quantile.type)` for the default method.
- `...` additional arguments affecting the summary produced.

**Details**

For factors, the frequency of the first `maxsum - 1` most frequent levels is shown, and the less frequent levels are summarized in "(Others)" (resulting in at most `maxsum` frequencies).

The functions `summary.lm` and `summary.glm` are examples of particular methods which summarize the results produced by `lm` and `glm`.
The form of the value returned by `summary` depends on the class of its argument. See the documentation of the particular methods for details of what is produced by that method.

The default method returns an object of class `c("summaryDefault","table")` which has specialized `format` and `print` methods. The `factor` method returns an integer vector.

The matrix and data frame methods return a matrix of class "table", obtained by applying `summary` to each column and collating the results.

References

See Also

`anova`, `summary.glm`, `summary.lm`.

Examples

```r
summary(attenu, digits = 4) #-> summary.data.frame(...), default precision
summary(attenu$station, maxsum = 20) #-> summary.factor(...)
```

```r
lst <- unclass(attenu$station) > 20 # logical with NAs
## summary.default() for logicals -- different from *.factor:
summary(lst)
summary(as.factor(lst))
```

---

**svd**

**Singular Value Decomposition of a Matrix**

**Description**

Compute the singular-value decomposition of a rectangular matrix.

**Usage**

```r
svd(x, nu = min(n, p), nv = min(n, p), LINPACK = FALSE)
La.svd(x, nu = min(n, p), nv = min(n, p))
```

**Arguments**

- **x**
  - a numeric or complex matrix whose SVD decomposition is to be computed. Logical matrices are coerced to numeric.

- **nu**
  - the number of left singular vectors to be computed. This must be between 0 and \( n = nrow(x) \).

- **nv**
  - the number of right singular vectors to be computed. This must be between 0 and \( p = ncol(x) \).

- **LINPACK**
  - logical. Defunct and an error.
Details

The singular value decomposition plays an important role in many statistical techniques. `svd` and `La.svd` provide two interfaces which differ in their return values.

Computing the singular vectors is the slow part for large matrices. The computation will be more efficient if both \(nu <= \min(n,p)\) and \(nv <= \min(n,p)\), and even more so if both are zero.

Unsuccessful results from the underlying LAPACK code will result in an error giving a positive error code (most often 1): these can only be interpreted by detailed study of the FORTRAN code but mean that the algorithm failed to converge.

Value

The SVD decomposition of the matrix as computed by LAPACK,

\[ X = UDV', \]

where \(U\) and \(V\) are orthogonal, \(V'\) means \(V\) transposed (and conjugated for complex input), and \(D\) is a diagonal matrix with the (non-negative) singular values \(D_{ii}\) in decreasing order. Equivalently, \(D = U'XV\), which is verified in the examples.

The returned value is a list with components

- **d** a vector containing the singular values of \(x\), of length \(\min(n,p)\), sorted decreasingly.
- **u** a matrix whose columns contain the left singular vectors of \(x\), present if \(nu > 0\). Dimension \(c(n,nu)\).
- **v** a matrix whose columns contain the right singular vectors of \(x\), present if \(nv > 0\). Dimension \(c(p,nv)\).

Recall that the singular vectors are only defined up to sign (a constant of modulus one in the complex case). If a left singular vector has its sign changed, changing the sign of the corresponding right vector gives an equivalent decomposition.

For `La.svd` the return value replaces \(v\) by \(vt\), the (conjugated if complex) transpose of \(v\).

Source

The main functions used are the LAPACK routines `DGESDD` and `ZGESDD`.

LAPACK is from [https://www.netlib.org/lapack/](https://www.netlib.org/lapack/) and its guide is listed in the references.

sweep

Examples

hilbert <- function(n) { i <- 1:n; 1 / outer(i - 1, i, "+") }
X <- hilbert(9)[, 1:6]
(s <- svd(X))
D <- diag(s$d)
s$u %*% D %*% t(s$v) # X = U D V'
t(s$u) %*% X %*% s$v # D = U' X V

sweep         Sweep out Array Summaries

Description

Return an array obtained from an input array by sweeping out a summary statistic.

Usage

sweep(x, MARGIN, STATS, FUN = "-", check.margin = TRUE, ...)

Arguments

x an array, including a matrix.
MARGIN a vector of indices giving the extent(s) of x which correspond to STATS. Where x has named dimnames, it can be a character vector selecting dimension names.
STATS the summary statistic which is to be swept out.
FUN the function to be used to carry out the sweep.
check.margin logical. If TRUE (the default), warn if the length or dimensions of STATS do not match the specified dimensions of x. Set to FALSE for a small speed gain when you know that dimensions match.
... optional arguments to FUN.

Details

FUN is found by a call to match.fun. As in the default, binary operators can be supplied if quoted or backquoted.

FUN should be a function of two arguments: it will be called with arguments x and an array of the same dimensions generated from STATS by aperm.

The consistency check among STATS, MARGIN and x is stricter if STATS is an array than if it is a vector. In the vector case, some kinds of recycling are allowed without a warning. Use sweep(x, MARGIN, as.array(STATS)) if STATS is a vector and you want to be warned if any recycling occurs.

Value

An array with the same shape as x, but with the summary statistics swept out.

References

See Also

apply on which sweep used to be based; scale for centering and scaling.

Examples

require(stats) # for median
med.att <- apply(attitude, 2, median)
sweep(data.matrix(attitude), 2, med.att) # subtract the column medians

## More sweeping:
A <- array(1:24, dim = 4:2)

## no warnings in normal use
sweep(A, 1, 5)
(A.min <- apply(A, 1, min)) # == 1:4
sweep(A, 1, A.min)
sweep(A, 1:2, apply(A, 1:2, median))

## warnings when mismatch
sweep(A, 1, 1:3) # STATS does not recycle
sweep(A, 1, 6:1) # STATS is longer

## exact recycling:
(sweep(A, 1, 1:2) # no warning
sweep(A, 1, as.array(1:2)) # warning

## Using named dimnames
dimnames(A) <- list(fee=1:4, fie=1:3, fum=1:2)

mn_fum_fie <- apply(A, c("fum", "fie"), mean)
mn_fum_fie
sweep(A, c("fum", "fie"), mn_fum_fie)

switch

Select One of a List of Alternatives

Description

switch evaluates EXPR and accordingly chooses one of the further arguments (in ...).

Usage

switch(EXPR, ...)

Arguments

EXPR an expression evaluating to a number or a character string.
...

the list of alternatives. If it is intended that EXPR has a character-string value these will be named, perhaps except for one alternative to be used as a 'default' value.
Details

switch works in two distinct ways depending whether the first argument evaluates to a character string or a number.

If the value of EXPR is not a character string it is coerced to integer. Note that this also happens for factors, with a warning, as typically the character level is meant. If the integer is between 1 and nargs()-1 then the corresponding element of ... is evaluated and the result returned: thus if the first argument is 3 then the fourth argument is evaluated and returned.

If EXPR evaluates to a character string then that string is matched (exactly) to the names of the elements in ... If there is a match then that element is evaluated unless it is missing, in which case the next non-missing element is evaluated, so for example switch("cc",a = 1,cc = ,cd = ,d = 2) evaluates to 2. If there is more than one match, the first matching element is used. In the case of no match, if there is an unnamed element of ... its value is returned. (If there is more than one such argument an error is signaled.)

The first argument is always taken to be EXPR: if it is named its name must (partially) match.

A warning is signaled if no alternatives are provided, as this is usually a coding error.

This is implemented as a primitive function that only evaluates its first argument and one other if one is selected.

Value

The value of one of the elements of ..., or NULL, invisibly (whenever no element is selected).

The result has the visibility (see invisible) of the element evaluated.

Warning

It is possible to write calls to switch that can be confusing and may not work in the same way in earlier versions of R. For compatibility (and clarity), always have EXPR as the first argument, naming it if partial matching is a possibility. For the character-string form, have a single unnamed argument as the default after the named values.

References

Examples

```r
require(stats)
centre <- function(x, type) {
  switch(type,
    mean = mean(x),
    median = median(x),
    trimmed = mean(x, trim = .1))
}
x <- rcauchy(10)
centre(x, "mean")
centre(x, "median")
centre(x, "trimmed")
ccc <- c("b","QQ","a","A","bb")
# note: cat() produces no output for NULL
for(ch in ccc)
```

cat(ch, ":", switch(EXPR = ch, a = 1, b = 2:3), "\n")
for(ch in ccc)
  cat(ch, ":", switch(EXPR = ch, a = A = 1, b = 2:3, "Otherwise: last"), ":\n")
## switch(f, *) with a factor f
ff <- gl(3, 1, labels=LETTERS[3:1])
ff[1] # C
## so one might expect " is C" here, but
switch(ff[1], A = "I am A", B="Bb..", C=" is C")# -> "I am A"
## so we give a warning
## Numeric EXPR does not allow a default value to be specified
## -- it is always NULL
for(i in c(-1:3, 9)) print(switch(i, 1, 2 , 3, 4))
## visibility
switch(1, invisible(pi), pi)
switch(2, invisible(pi), pi)

---

**Syntax**

**Operator Syntax and Precedence**

**Description**

Outlines R syntax and gives the precedence of operators.

**Details**

The following unary and binary operators are defined. They are listed in precedence groups, from highest to lowest.

```
:: ::::  access variables in a namespace
$ @    component / slot extraction
[ [ ]  indexing
^      exponentiation (right to left)
- +    unary minus and plus
:      sequence operator
%any% special operators (including %% and %/%)
* /    multiply, divide
+ -    (binary) add, subtract
< > <= >= !=  ordering and comparison
!      negation
& &&   and
| ||   or
~      as in formulae
-> ->>> rightwards assignment
<= <<= assignment (right to left)
=      assignment (right to left)
?      help (unary and binary)
```

Within an expression operators of equal precedence are evaluated from left to right except where
indicated. (Note that = is not necessarily an operator.)

The binary operators ::, :::, $ and @ require names or string constants on the right hand side, and
the first two also require them on the left.

The links in the See Also section cover most other aspects of the basic syntax.

Note

There are substantial precedence differences between R and S. In particular, in S ? has the same
precedence as (binary) + - and & & || have equal precedence.

References

Brooks/Cole.

See Also

Arithmetic, Comparison, Control, Extract, Logic, NumericConstants, Paren, Quotes, Reserved.

The ‘R Language Definition’ manual.

Examples

### Logical AND ("&&") has higher precedence than OR ("||"):
TRUE || TRUE && FALSE  # is the same as
TRUE || (TRUE && FALSE) # and different from
(TRUE || TRUE) && FALSE

### Special operators have higher precedence than "!" (logical NOT).
## You can use this for %in% :
! 1:10 %in% c(2, 3, 5, 7) # same as !(1:10 %in% c(2, 3, 5, 7))
## but we strongly advise to use the "!( ... )" form in this case!

## '=-' has lower precedence than '<-' ... so you should not mix them
## (and '<-' is considered better style anyway):
## Consequently, this gives a ("non-catchable") error
x <- y = 5  #> Error in (x <- y) = 5 : ....

---

**Sys.getenv**  
*Get Environment Variables*

**Description**

Sys.getenv obtains the values of the environment variables.

**Usage**

Sys.getenv(x = NULL, unset = "", names = NA)
Sys.getpid

Get the Process ID of the R Session

Description

Get the process ID of the R Session. It is guaranteed by the operating system that two R sessions running simultaneously will have different IDs, but it is possible that R sessions running at different times will have the same ID.

Sys.getpid

Get the Process ID of the R Session

Description

Get the process ID of the R Session. It is guaranteed by the operating system that two R sessions running simultaneously will have different IDs, but it is possible that R sessions running at different times will have the same ID.
Sys.glob

Usage

Sys.getpid()

Value

An integer, often between 1 and 32767 under Unix-alikes (but for example FreeBSD and macOS use IDs up to 99999) and a positive integer (up to 32767) under Windows.

Examples

Sys.getpid()

## Show files opened from this R process
if(.Platform$OS.type == "unix") ## on Unix-alikes such Linux, macOS, FreeBSD:
  system(paste("lsof -p", Sys.getpid()))

Sys.glob

Wildcard Expansion on File Paths

Description

Function to do wildcard expansion (also known as 'globbing') on file paths.

Usage

Sys.glob(paths, dirmark = FALSE)

Arguments

paths character vector of patterns for relative or absolute filepaths. Missing values will be ignored.

dirmark logical: should matches to directories from patterns that do not already end in / have a slash appended? May not be supported on all platforms.

Details

This expands tilde (see tilde expansion) and wildcards in file paths. For precise details of wildcards expansion, see your system’s documentation on the glob system call. There is a POSIX 1003.2 standard (see https://pubs.opengroup.org/onlinepubs/9699919799/functions/glob.html) but some OSes will go beyond this.

All systems should interpret * (match zero or more characters), ? (match a single character) and (probably) [ (begin a character class or range). The handling of paths ending with a separator is system-dependent. On a POSIX-2008 compliant OS they will match directories (only), but as they are not valid filepaths on Windows, they match nothing there. (Earlier POSIX standards allowed them to match files.)

The rest of these details are indicative (and based on the POSIX standard).

If a filename starts with . this may need to be matched explicitly: for example Sys.glob("*.RData") may or may not match `.RData` but will not usually match `.aa.RData`. Note that this is platform-dependent: e.g. on Solaris Sys.glob("*.*) matches ‘.’ and ‘.’.
[ begins a character class. If the first character in [...] is not !, this is a character class which matches a single character against any of the characters specified. The class cannot be empty, so ] can be included provided it is first. If the first character is !, the character class matches a single character which is *none* of the specified characters. Whether . in a character class matches a leading . in the filename is OS-dependent.

Character classes can include ranges such as [A-Z]: include - as a character by having it first or last in a class. (The interpretation of ranges should be locale-specific, so the example is not a good idea in an Estonian locale.)

One can remove the special meaning of ?, *, and [ by preceding them by a backslash (except within a character class).

**Value**

A character vector of matched file paths. The order is system-specific (but in the order of the elements of `paths`): it is normally collated in either the current locale or in byte (ASCII) order; however, on Windows collation is in the order of Unicode points.

Directory errors are normally ignored, so the matches are to accessible file paths (but not necessarily accessible files).

**See Also**

`path.expand`

Quotes for handling backslashes in character strings.

**Examples**

```r
Sys.glob(file.path(R.home(), "library", "*", "R", "*.rdx"))
```

---

### Extract System and User Information

**Description**

Reports system and user information.

**Usage**

`Sys.info()`

**Details**

This uses POSIX or Windows system calls. Note that OS names might not be what you expect: for example macOS identifies itself as ‘Darwin’ and Solaris as ‘SunOS’.

`Sys.info()` returns details of the platform R is running on, whereas `R.version` gives details of the platform R was built on: the release and version may well be different.
Value

A character vector with fields

- sysname: The operating system name.
- release: The OS release.
- version: The OS version.
- nodename: A name by which the machine is known on the network (if any).
- machine: A concise description of the hardware, often the CPU type.
- login: The user’s login name, or "unknown" if it cannot be ascertained.
- user: The name of the real user ID, or "unknown" if it cannot be ascertained.
- effective_user: The name of the effective user ID, or "unknown" if it cannot be ascertained. This may differ from the real user in ‘set-user-ID’ processes.

The first five fields come from the uname(2) system call. The login name comes from getlogin(2), and the user names from getpwuid(getuid()) and getpwuid(geteuid())

Note

The meaning of release and version is system-dependent: on a Unix-alike they normally refer to the kernel. There, usually release contains a numeric version and version gives additional information. Examples for release:

- "4.17.11-200.fc28.x86_64" # Linux (Fedora)
- "3.16.0-5-amd64" # Linux (Debian)
- "17.7.0" # macOS 10.13.6
- "5.11" # Solaris

There is no guarantee that the node or login or user names will be what you might reasonably expect. (In particular on some Linux distributions the login name is unknown from sessions with re-directed inputs.)

The use of alternatives such as system("whoami") is not portable: the POSIX command system("id") is much more portable on Unix-alikes, provided only the POSIX options ‘-G[gu][nr]’ are used (and not the many BSD and GNU extensions). whoami is equivalent to id -un (on Solaris, /usr/xpg4/bin/id -un).

See Also

.Platform, and R.version. sessionInfo() gives a synopsis of both your system and the R session (and gives the OS version in a human-readable form).

Examples

Sys.info()
## An alternative (and probably better) way to get the login name on Unix
Sys.getenv("LOGNAME")
Sys.localeconv

Find Details of the Numerical and Monetary Representations in the Current Locale

Description

Get details of the numerical and monetary representations in the current locale.

Usage

Sys.localeconv()

Details

Normally R is run without looking at the value of LC_NUMERIC, so the decimal point remains ".". So the first three of these components will only be useful if you have set the locale category LC_NUMERIC using Sys.setlocale in the current R session (when R may not work correctly).

The monetary components will only be set to non-default values (see the ‘Examples’ section) if the LC.MONETARY category is set. It often is not set: set the examples for how to trigger setting it.

Value

A character vector with 18 named components. See your ISO C documentation for details of the meaning.

It is possible to compile R without support for locales, in which case the value will be NULL.

See Also

Sys.setlocale for ways to set locales.

Examples

Sys.localeconv()
## The results in the C locale are
## decimal_point thousands_sep grouping int_curr_symbol
## "." "" " ""
## currency_symbol mon_decimal_point mon_thousands_sep mon_grouping
## "" " " " ""
## positive_sign negative_sign int_frac_digits frac_digits
## "" " "127" 127"
## p_cs_precedes p_sep_by_space n_cs_precedes n_sep_by_space
## "127" 127" 127" "127"
## p_sign_posn n_sign_posn
## "127" 127"

## Now try your default locale (which might be "C").
old <- Sys.getlocale()
## The category may not be set:
## the following may do so, but it might not be supported.
Sys.setlocale("LC_MONETARY", locale = ")
Sys.localeconv()
## or set an appropriate value yourself, e.g.
Sys.setlocale("LC_MONETARY", "de_AT")
Sys.localeconv()
Sys.setlocale(locale = old)

## Not run: read.table("foo", dec=Sys.localeconv()["decimal_point"])
sys.status() returns a list with components sys.calls, sys.parents and sys.frames, the results of calls to those three functions (which this will include the call to sys.status: see the first example).

sys.on.exit() returns the expression stored for use by on.exit in the function currently being evaluated. (Note that this differs from S, which returns a list of expressions for the current frame and its parents.)

parent.frame(n) is a convenient shorthand for sys.frame(sys.parent(n)) (implemented slightly more efficiently).

Value

sys.call returns a call, sys.function a function definition, and sys.frame and parent.frame return an environment.

For the other functions, see the ‘Details’ section.

Note

Strictly, sys.parent and parent.frame refer to the context of the parent interpreted function. So internal functions (which may or may not set contexts and so may or may not appear on the call stack) may not be counted, and S3 methods can also do surprising things.

Beware of the effect of lazy evaluation: these two functions look at the call stack at the time they are evaluated, not at the time they are called. Passing calls to them as function arguments is unlikely to be a good idea.

References

See Also

eval for a usage of sys.frame and parent.frame.

Examples

require(utils)

## Note: the first two examples will give different results
## if run by example().
ff <- function(x) gg(x)
gg <- function(y) sys.status()
str(ff(1))

gg <- function(y) {
  ggg <- function() {
    cat("current frame is", sys.nframe(), "\n")
    cat("parents are", sys.parents(), "\n")
    print(sys.function(0)) # ggg
    print(sys.function(2)) # gg
  }
  if(y > 0) gg(y-1) else ggg()
}
gg(3)
Sys.readlink

Read File Symbolic Links

Description

Find out if a file path is a symbolic link, and if so what it is linked to, via the system call readlink. Symbolic links are a POSIX concept, not implemented on Windows but for most filesystems on Unix-alikes.

Usage

Sys.readlink(paths)

Arguments

paths character vector of file paths. Tilde expansion is done: see path.expand.
Value

A character vector of the same length as paths. The entries are the path of the file linked to, "" if the path is not a symbolic link, and NA if there is an error (e.g., the path does not exist or cannot be converted to the native encoding).

On platforms without the readlink system call, all elements are "".

See Also

`file.symlink` for the creation of symbolic links (and their Windows analogues), `file.info`

Examples

```r
##' To check if files (incl. directories) are symbolic links:
is.symlink <- function(paths) isTRUE(nzchar(Sys.readlink(paths), keepNA=TRUE))
## will return all FALSE when the platform has no `readlink` system call.
is.symlink("/foo/bar")
```

Sys.setenv

Set or Unset Environment Variables

Description

`Sys.setenv` sets environment variables (for other processes called from within R or future calls to `Sys.getenv` from this R process).

`Sys.unsetenv` removes environment variables.

Usage

```r
Sys.setenv(...)  
 Sys.unsetenv(x)
```

Arguments

...  
 named arguments with values coercible to a character string.

x  
 a character vector, or an object coercible to character.

Details

Non-standard R names must be quoted in `Sys.setenv`: see the examples. Most platforms (and POSIX) do not allow names containing "=". Windows does, but the facilities provided by R may not handle these correctly so they should be avoided. Most platforms allow setting an environment variable to "", but Windows does not and there `Sys.setenv(F00 = "")` unsets F00.

There may be system-specific limits on the maximum length of the values of individual environment variables or of names+values of all environment variables.

Recent versions of Windows have a maximum length of 32,767 characters for a environment variable; however cmd.exe has a limit of 8192 characters for a command line, hence set can only set 8188.
Value

A logical vector, with elements being true if (un)setting the corresponding variable succeeded. (For Sys.unsetenv this includes attempting to remove a non-existent variable.)

Note

On Unix-alikes, if Sys.unsetenv is not supported, it will at least try to set the value of the environment variable to "", with a warning.

See Also

Sys.getenv, Startup for ways to set environment variables for the R session.

setwd for the working directory.

The help for ‘environment variables’ lists many of the environment variables used by R.

Examples

print(Sys.setenv(R_TEST = "testit", "A+C" = 123))  # 'A+C' could also be used
Sys.getenv("R_TEST")
Sys.unsetenv("R_TEST")  # on Unix-alike may warn and not succeed
Sys.getenv("R_TEST", unset = NA)

Description

Uses system calls to set the times on a file or directory.

Usage

Sys.setFileTime(path, time)

Arguments

path          A character vector containing file or directory paths.
time          A date-time of class "POSIXct" or an object which can be coerced to one. Fractions of a second may be ignored. Recycled along paths.

Details

This attempts sets the file time to the value specified.

On a Unix-alike it uses the system call utimensat if that is available, otherwise utimes or utime. On a POSIX file system it sets both the last-access and modification times. Fractional seconds will set as from R 3.4.0 on OSes with the requisite system calls and suitable filesystems.

On Windows it uses the system call SetFileTime to set the ‘last write time’. Some Windows file systems only record the time at a resolution of two seconds.

Sys.setFileTime has been vectorized in R 3.6.0. Earlier versions of R required path and time to be vectors of length one.
Sys.sleep

suspend execution for a time interval

Description

Suspend execution of \texttt{R} expressions for a specified time interval.

Usage

\texttt{Sys.sleep(time)}

Arguments

time \hspace{1cm} The time interval to suspend execution for, in seconds.

Details

Using this function allows \texttt{R} to temporarily be given very low priority and hence not to interfere with more important foreground tasks. A typical use is to allow a process launched from \texttt{R} to set itself up and read its input files before \texttt{R} execution is resumed.

The intention is that this function suspends execution of \texttt{R} expressions but wakes the process up often enough to respond to GUI events, typically every half second. It can be interrupted (e.g. by ‘\texttt{Ctrl-C}’ or ‘\texttt{Esc}’ at the \texttt{R} console).

There is no guarantee that the process will sleep for the whole of the specified interval (sleep might be interrupted), and it may well take slightly longer in real time to resume execution.

time must be non-negative (and not \texttt{NA} nor \texttt{NaN}): \texttt{Inf} is allowed (and might be appropriate if the intention is to wait indefinitely for an interrupt). The resolution of the time interval is system-dependent, but will normally be 20ms or better. (On modern Unix-alikes it will be better than 1ms.)

Value

Invisible \texttt{NULL}.

Note

Despite its name, this is not currently implemented using the \texttt{sleep} system call (although on Windows it does make use of \texttt{Sleep}).

Examples

\begin{verbatim}
  testit <- function(x)
  {
    p1 <- proc.time()
    Sys.sleep(x)
    proc.time() - p1 \# The cpu usage should be negligible
  }
  testit(3.7)
\end{verbatim}
Parse and Evaluate Expressions from a File

Description

Parses expressions in the given file, and then successively evaluates them in the specified environment.

Usage

```r
sys.source(file, envir = baseenv(), chdir = FALSE,
keep.source = getOption("keep.source.pkgs"),
keep.parse.data = getOption("keep.parse.data.pkgs"),
toplevel.env = as.environment(envir))
```

Arguments

- **file**: a character string naming the file to be read from
- **envir**: an R object specifying the environment in which the expressions are to be evaluated. May also be a list or an integer. The default value NULL corresponds to evaluation in the base environment. This is probably not what you want; you should typically supply an explicit envir argument.
- **chdir**: logical; if TRUE, the R working directory is changed to the directory containing file for evaluating.
- **keep.source**: logical. If TRUE, functions keep their source including comments, see `options(keep.source = *)` for more details.
- **keep.parse.data**: logical. If TRUE and keep.source is also TRUE, functions keep parse data with their source, see `options(keep.parse.data = *)` for more details.
- **toplevel.env**: an R environment to be used as top level while evaluating the expressions. This argument is useful for frameworks running package tests; the default should be used in other cases

Details

For large files, keep.source = FALSE may save quite a bit of memory. Disabling only parse data via keep.parse.data = FALSE can already save a lot.

In order for the code being evaluated to use the correct environment (for example, in global assignments), source code in packages should call `topenv()`, which will return the namespace, if any, the environment set up by sys.source, or the global environment if a saved image is being used.

See Also

`source`, and `library` which uses `sys.source`. 
Examples

```r
## a simple way to put some objects in an environment
## high on the search path
tmp <- tempfile()
writeLines("aaa <- pi", tmp)
env <- attach(NULL, name = "myenv")
sys.source(tmp, env)
unlink(tmp)
search()
aaa
detach("myenv")
```

---

Sys.time

### Get Current Date and Time

**Description**

`Sys.time` and `Sys.Date` returns the system’s idea of the current date with and without time.

**Usage**

```r
Sys.time()
Sys.Date()
```

**Details**

`Sys.time` returns an absolute date-time value which can be converted to various time zones and may return different days.

`Sys.Date` returns the current day in the current time zone.

**Value**

`Sys.time` returns an object of class "POSIXct" (see `DateTimeClasses`). On almost all systems it will have sub-second accuracy, possibly microseconds or better. On Windows it increments in clock ticks (usually 1/60 of a second) reported to millisecond accuracy.

`Sys.Date` returns an object of class "Date" (see `Date`).

**Note**

`Sys.time` may return fractional seconds, but they are ignored by the default conversions (e.g., printing) for class "POSIXct". See the examples and `format.POSIXct` for ways to reveal them.

**See Also**

- `date` for the system time in a fixed-format character string.
- `Sys.timezone`.
- `system.time` for measuring elapsed/CPU time of expressions.
Sys.which

Examples

Sys.time()
## print with possibly greater accuracy:
op <- options(digits.secs = 6)
Sys.time()
options(op)

## locale-specific version of date()
format(Sys.time(), "%a %b %d %X %Y")
Sys.Date()

Sys.which

Find Full Paths to Executables

Description

This is an interface to the system command which, or to an emulation on Windows.

Usage

Sys.which(names)

Arguments

names Character vector of names or paths of possible executables.

Details

The system command `which` reports on the full path names of an executable (including an executable script) as would be executed by a shell, accepting either absolute paths or looking on the path.

On Windows an ‘executable’ is a file with extension ‘.exe’, ‘.com’, ‘.cmd’ or ‘.bat’. Such files need not actually be executable, but they are what system tries.

On a Unix-alike the full path to `which` (usually ‘/usr/bin/which’) is found when R is installed.

Value

A character vector of the same length as names, named by names. The elements are either the full path to the executable or some indication that no executable of that name was found. Typically the indication is “”, but this does depend on the OS (and the known exceptions are changed to “”). Missing values in names have missing return values.

On Windows the paths will be short paths (8+3 components, no spaces) with \ as the path delimiter.

Note

Except on Windows this calls the system command `which`: since that is not part of e.g. the POSIX standards, exactly what it does is OS-dependent. It will usually do tilde-expansion and it may make use of csh aliases.
system

Examples

## the first two are likely to exist everywhere
## texi2dvi exists on most Unix-alikes and under MiKTeX
Sys.which(c("ftp", "ping", "texi2dvi", "this-does-not-exist"))

system

Invoke a System Command

Description

system invokes the OS command specified by command.

Usage

system(command, intern = FALSE,
    ignore.stdout = FALSE, ignore.stderr = FALSE,
    wait = TRUE, input = NULL, show.output.on.console = TRUE,
    minimized = FALSE, invisible = TRUE, timeout = 0)

Arguments

command the system command to be invoked, as a character string.
intern a logical (not NA) which indicates whether to capture the output of the command as an R character vector.
ignore.stdout, ignore.stderr a logical (not NA) indicating whether messages written to 'stdout' or 'stderr' should be ignored.
wait a logical (not NA) indicating whether the R interpreter should wait for the command to finish, or run it asynchronously. This will be ignored (and the interpreter will always wait) if intern = TRUE. When running the command asynchronously, no output will be displayed on the Rgui console in Windows (it will be dropped, instead).
input if a character vector is supplied, this is copied one string per line to a temporary file, and the standard input of command is redirected to the file.
timeout timeout in seconds, ignored if 0. This is a limit for the elapsed time running command in a separate process. Fractions of seconds are ignored.
show.output.on.console, minimized, invisible arguments that are accepted on Windows but ignored on this platform, with a warning.

Details

This interface has become rather complicated over the years: see system2 for a more portable and flexible interface which is recommended for new code.

command is parsed as a command plus arguments separated by spaces. So if the path to the command (or a single argument such as a file path) contains spaces, it must be quoted e.g. by shQuote. Unix-alikes pass the command line to a shell (normally '/bin/sh', and POSIX requires that shell), so command can be anything the shell regards as executable, including shell scripts, and it can contain multiple commands separated by ;.
On Windows, `system` does not use a shell and there is a separate function `shell` which passes command lines to a shell.

If `intern` is TRUE then `popen` is used to invoke the command and the output collected, line by line, into an R `character` vector. If `intern` is FALSE then the C function `system` is used to invoke the command.

`wait` is implemented by appending `&` to the command: this is in principle shell-dependent, but required by POSIX and so widely supported.

When `timeout` is non-zero, the command is terminated after the given number of seconds. The termination works for typical commands, but is not guaranteed: it is possible to write a program that would keep running after the time is out. Timeouts can only be set with `wait = TRUE`.

Timeouts cannot be used with interactive commands: the command is run with standard input redirected from `/dev/null` and it must not modify terminal settings. As long as the `tostop` option is disabled, which it usually is by default, the executed command may write to standard output and standard error. One cannot rely on that the execution time of the child processes will be included into `user.child` and `sys.child` element of `proc_time` returned by `proc.time`. For the time to be included, all child processes have to be waited for by their parents, which has to be implemented in the parent applications.

The ordering of arguments after the first two has changed from time to time: it is recommended to name all arguments after the first.

There are many pitfalls in using `system` to ascertain if a command can be run — `Sys.which` is more suitable.

### Value

If `intern = TRUE`, a character vector giving the output of the command, one line per character string. (Output lines of more than 8095 bytes will be split on some systems.) If the command could not be run an R error is generated. If `command` runs but gives a non-zero exit status this will be reported with a warning and in the attribute "status" of the result: an attribute "errmsg" may also be available.

If `intern = FALSE`, the return value is an error code (0 for success), given the invisible attribute (so needs to be printed explicitly). If the command could not be run for any reason, the value is 127 and a warning is issued (as from R 3.5.0). Otherwise if `wait = TRUE` the value is the exit status returned by the command, and if `wait = FALSE` it is 0 (the conventional success value).

If the command times out, a warning is reported and the exit status is 124.

### Stdout and stderr

For command-line R, error messages written to `stderr` will be sent to the terminal unless `ignore.stderr = TRUE`. They can be captured (in the most likely shells) by

```r
system("some command 2>&1", intern = TRUE)
```

For GUIs, what happens to output sent to `stdout` or `stderr` if `intern = FALSE` is interface-specific, and it is unsafe to assume that such messages will appear on a GUI console (they do on the macOS GUI’s console, but not on some others).

### Differences between Unix and Windows

How processes are launched differs fundamentally between Windows and Unix-alike operating systems, as do the higher-level OS functions on which this R function is built. So it should not be surprising that there are many differences between OSes in how `system` behaves. For the benefit of programmers, the more important ones are summarized in this section.
The most important difference is that on a Unix-alike system launches a shell which then runs command. On Windows the command is run directly – use shell for an interface which runs command via a shell (by default the Windows shell cmd.exe, which has many differences from a POSIX shell).

This means that it cannot be assumed that redirection or piping will work in system (redirection sometimes does, but we have seen cases where it stopped working after a Windows security patch), and system2 (or shell) must be used on Windows.

What happens to stdout and stderr when not captured depends on how R is running: Windows batch commands behave like a Unix-alike, but from the Windows GUI they are generally lost. system(intern = TRUE) captures 'stderr' when run from the Windows GUI console unless ignore.stderr = TRUE.

The behaviour on error is different in subtle ways (and has differed between R versions).

The quoting conventions for command differ, but shQuote is a portable interface.

Arguments show.output.on.console, minimized, invisible only do something on Windows (and are most relevant to Rgui there).

See Also

man system and man sh for how this is implemented on the OS in use.

.Platform for platform-specific variables.

pipe to set up a pipe connection.

Examples

# list all files in the current directory using the -F flag
## Not run: system("ls -F")

# t1 is a character vector, each element giving a line of output from who
# (if the platform has who)
t1 <- try(system("who", intern = TRUE))

try(system("ls fizzlipuzzli", intern = TRUE, ignore.stderr = TRUE))

# zero-length result since file does not exist, and will give warning.

system.file Find Names of R System Files

Description

Finds the full file names of files in packages etc.

Usage

system.file(..., package = "base", lib.loc = NULL,
            mustWork = FALSE)
Arguments

... character vectors, specifying subdirectory and file(s) within some package. The default, none, returns the root of the package. Wildcards are not supported.
package a character string with the name of a single package. An error occurs if more than one package name is given.
lib.loc a character vector with path names of R libraries. See ‘Details’ for the meaning of the default value of NULL.
mustWork logical. If TRUE, an error is given if there are no matching files.

Details

This checks the existence of the specified files with file.exists. So file paths are only returned if there are sufficient permissions to establish their existence.

The unnamed arguments in ... are usually character strings, but if character vectors they are recycled to the same length.

This uses find.package to find the package, and hence with the default lib.loc = NULL looks first for attached packages then in each library listed in .libPaths(). Note that if a namespace is loaded but the package is not attached, this will look only on .libPaths().

Value

A character vector of positive length, containing the file paths that matched ..., or the empty string, "", if none matched (unless mustWork = TRUE).

If matching the root of a package, there is no trailing separator.

system.file() with no arguments gives the root of the base package.

See Also

R.home for the root directory of the R installation, list.files.
Sys.glob to find paths via wildcards.

Examples

system.file()  # The root of the 'base' package
system.file(package = "stats")  # The root of package 'stats'
system.file("INDEX")
system.file("help", "AnIndex", package = "splines")

system.time

<table>
<thead>
<tr>
<th>CPU Time Used</th>
</tr>
</thead>
</table>

Description

Return CPU (and other) times that expr used.

Usage

system.time(expr, gcFirst = TRUE)
system2

Invoke a System Command

Description

system2 invokes the OS command specified by command.
Usage

```r
system2(command, args = character(),
    stdout = "", stderr = "", stdin = "", input = NULL,
    env = character(), wait = TRUE,
    minimized = FALSE, invisible = TRUE, timeout = 0)
```

Arguments

- **command**: the system command to be invoked, as a character string.
- **args**: a character vector of arguments to `command`.
- **stdout, stderr**: where output to `stdout` or `stderr` should be sent. Possible values are "", to the R console (the default), NULL or FALSE (discard output), TRUE (capture the output in a character vector) or a character string naming a file.
- **stdin**: should input be diverted? "" means the default, alternatively a character string naming a file. Ignored if input is supplied.
- **input**: if a character vector is supplied, this is copied one string per line to a temporary file, and the standard input of `command` is redirected to the file.
- **env**: character vector of name=value strings to set environment variables.
- **wait**: a logical (not NA) indicating whether the R interpreter should wait for the command to finish, or run it asynchronously. This will be ignored (and the interpreter will always wait) if `stdout = TRUE` or `stderr = TRUE`. When running the command asynchronously, no output will be displayed on the Rgui console in Windows (it will be dropped, instead).
- **timeout**: timeout in seconds, ignored if 0. This is a limit for the elapsed time running command in a separate process. Fractions of seconds are ignored.
- **minimized, invisible**: arguments that are accepted on Windows but ignored on this platform, with a warning.

Details

Unlike `system`, command is always quoted by `shQuote`, so it must be a single command without arguments.

For details of how command is found see `system`.

On Windows, `env` is only supported for commands such as `R` and `make` which accept environment variables on their command line.

Some Unix commands (such as some implementations of `ls`) change their output if they consider it to be piped or redirected: `stdout = TRUE` uses a pipe whereas `stdout = "some_file.name"` uses redirection.

Because of the way it is implemented, on a Unix-alike `stderr = TRUE` implies `stdout = TRUE`: a warning is given if this is not what was specified.

When `timeout` is non-zero, the command is terminated after the given number of seconds. The termination works for typical commands, but is not guaranteed: it is possible to write a program that would keep running after the time is out. Timeouts can only be set with `wait = TRUE`.

Timeouts cannot be used with interactive commands: the command is run with standard input redirected from `/dev/null` and it must not modify terminal settings. As long as tty `tostop` option is disabled, which it usually is by default, the executed command may write to standard output and standard error.
Value

If stdout = TRUE or stderr = TRUE, a character vector giving the output of the command, one line per character string. (Output lines of more than 8095 bytes will be split.) If the command could not be run an \texttt{R} error is generated. If command runs but gives a non-zero exit status this will be reported with a warning and in the attribute "status" of the result: an attribute "errmsg" may also be available.

In other cases, the return value is an error code (0 for success), given the invisible attribute (so needs to be printed explicitly). If the command could not be run for any reason, the value is 127 and a warning is issued (as from \texttt{R} 3.5.0). Otherwise if wait = TRUE the value is the exit status returned by the command, and if wait = FALSE it is 0 (the conventional success value).

If the command times out, a warning is issued and the exit status is 124.

Note

\texttt{system2} is a more portable and flexible interface than \texttt{system}. It allows redirection of output without needing to invoke a shell on Windows, a portable way to set environment variables for the execution of command, and finer control over the redirection of stdout and stderr. Conversely, \texttt{system} (and shell on Windows) allows the invocation of arbitrary command lines.

There is no guarantee that if stdout and stderr are both TRUE or the same file that the two streams will be interleaved in order. This depends on both the buffering used by the command and the OS.

\texttt{system}.

---

\texttt{t} \hspace{1cm} \textit{Matrix Transpose}

Description

Given a matrix or \texttt{data.frame} \texttt{x}, \texttt{t} returns the transpose of \texttt{x}.

Usage

\texttt{t(x)}

Arguments

\texttt{x} \hspace{1cm} a matrix or data frame, typically.

Details

This is a generic function for which methods can be written. The description here applies to the default and "data.frame" methods.

A data frame is first coerced to a matrix: see \texttt{as.matrix}. When \texttt{x} is a vector, it is treated as a column, i.e., the result is a 1-row matrix.

Value

A matrix, with \texttt{dim} and \texttt{dimnames} constructed appropriately from those of \texttt{x}, and other attributes except names copied across.
Note

The conjugate transpose of a complex matrix $A$, denoted $A^H$ or $A^*$, is computed as $\text{Conj}(t(A))$.

References

See Also

aperm for permuting the dimensions of arrays.

Examples

```r
a <- matrix(1:30, 5, 6)
ta <- t(a) #-- i.e., a[i, j] == ta[j, i] for all i,j :
for(j in seq(ncol(a)))
  if(! all(a[, j] == ta[j, ])) stop("wrong transpose")
```

Description

table uses the cross-classifying factors to build a contingency table of the counts at each combination of factor levels.

Usage

```r
table(...,
exclude = if (useNA == "no") c(NA, NaN),
useNA = c("no", "ifany", "always"),
dnn = list.names(...), deparse.level = 1)
as.table(x, ...)
is.table(x)
```

Arguments

- `...` one or more objects which can be interpreted as factors (including character strings), or a list (or data frame) whose components can be so interpreted. (For as.table, arguments passed to specific methods; for as.data.frame, unused.)
- `exclude` levels to remove for all factors in .... If it does not contain NA and useNA is not specified, it implies useNA = "ifany". See ‘Details’ for its interpretation for non-factor arguments.
- `useNA` whether to include NA values in the table. See ‘Details’. Can be abbreviated.
The names to be given to the dimensions in the result (the `dimnames names`).

deparse.level controls how the default `dnn` is constructed. See ‘Details’.

`x` an arbitrary R object, or an object inheriting from class "table" for the
as.data.frame method. Note that as.data.frame.table(x, ...) may be called
explicitly for non-table x for “reshaping” arrays.

`row.names` a character vector giving the row names for the data frame.

`responseName` The name to be used for the column of table entries, usually counts.

`stringsAsFactors` logical: should the classifying factors be returned as factors (the default) or
character vectors?

`sep, base` passed to `provideDimnames`.

Details

If the argument `dnn` is not supplied, the internal function `list.names` is called to compute the
‘dimnames names’. If the arguments in ... are named, those names are used. For the remaining
arguments, `deparse.level = 0` gives an empty name, `deparse.level = 1` uses the supplied argu-
ment if it is a symbol, and `deparse.level = 2` will deparse the argument.

Only when `exclude` is specified (i.e., not by default) and non-empty, will `table` potentially drop
levels of factor arguments.

`useNA` controls if the table includes counts of NA values: the allowed values correspond to never
("no"), only if the count is positive ("ifany") and even for zero counts ("always"). Note the
somewhat “pathological” case of two different kinds of NAs which are treated differently, depending
on both `useNA` and `exclude`, see `d.patho` in the ‘Examples’ below.

Both `exclude` and `useNA` operate on an “all or none” basis. If you want to control the dimensions
of a multiway table separately, modify each argument using `factor` or `addNA`.

Non-factor arguments `a` are coerced via `factor(a, exclude=exclude)`. Since R 3.4.0, care is taken
not to count the excluded values (where they were included in the NA count, previously).

The summary method for class "table" (used for objects created by `table` or `xtabs`) which gives
basic information and performs a chi-squared test for independence of factors (note that the function
`chisq.test` currently only handles 2-d tables).

Value

table() returns a contingency table, an object of class "table", an array of integer values. Note
that unlike S the result is always an array, a 1D array if one factor is given.

as.table and is.table coerce to and test for contingency table, respectively.

The as.data.frame method for objects inheriting from class "table" can be used to convert the
array-based representation of a contingency table to a data frame containing the classifying factors
and the corresponding entries (the latter as component named by `responseName`). This is the inverse
of `xtabs`.

References

Brooks/Cole.
See Also

tabulate is the underlying function and allows finer control.

Use ftable for printing (and more) of multidimensional tables. margin.table, prop.table, addmargins.
addNA for constructing factors with NA as a level.
xtabs for cross tabulation of data frames with a formula interface.

Examples

require(stats) # for rpois and xtabs
## Simple frequency distribution
table(rpois(100, 5))
## Check the design:
with(warpbreaks, table(wool, tension))
table(state.division, state.region)

# simple two-way contingency table
with(airquality, table(cut(Temp, quantile(Temp)), Month))

a <- letters[1:3]
table(a, sample(a))  # dnn is c("a", "")
table(a, sample(a), deparse.level = 0)  # dnn is c("", "")
table(a, sample(a), deparse.level = 2)  # dnn is c("a", "sample(a)")

## xtabs() <-> as.data.frame.table() :
UCBAdmissions ## already a contingency table
DF <- as.data.frame(UCBAdmissions)
class(tab <- xtabs(Freq ~ ., DF)) # xtabs & table
all(tab == UCBAdmissions)
all.equal(dimnames(tab), dimnames(UCBAdmissions))

a <- rep(c(NA, 1/0:3), 10)
table(a)  # does not report NA's
table(a, exclude = NULL)  # reports NA's
b <- factor(rep(c("A","B","C"), 10))
table(b)
table(b, exclude = "B")
d <- factor(rep(c("A","B","C"), 10), levels = c("A","B","C","D","E"))
table(d, exclude = "B")
print(table(b, d), zero.print = ".")

## NA counting:
is.na(d) <- 3:4
d. <- addNA(d)
d.[1:7]
table(d.) # ", exclude = NULL" is not needed
## i.e., if you want to count the NA's of 'd', use
table(d, useNA = "ifany")

## "pathological" case:
d.patho <- addNA(c(1,NA,1:2,1:3)[-7]; is.na(d.patho) <- 3:4
d.patho
## just 3 consecutive NA's ? --- well, have *two* kinds of NAs here :
as.integer(d.patho) # 1 4 NA NA 1 2
## In R >= 3.4.0, table() allows to differentiate:
```r
table(d.patho)  # counts the "unusual" NA
table(d.patho, useNA = "ifany")  # counts all three
```
```r
table(d.patho, exclude = NULL)  # (ditto)
table(d.patho, exclude = NA)  # counts none
```

## Two-way tables with NA counts. The 3rd variant is absurd, but shows
## something that cannot be done using exclude or useNA.
```r
with(airquality,
  table(OzHi = Ozone > 80, Month, useNA = "ifany"))
with(airquality,
  table(OzHi = Ozone > 80, Month, useNA = "always"))
with(airquality,
  table(OzHi = Ozone > 80, addNA(Month)))
```

---

### Tabulate for Vectors

#### Description

`tabulate` takes the integer-valued vector `bin` and counts the number of times each integer occurs in it.

#### Usage

```r
tabulate(bin, nbins = max(1, bin, na.rm = TRUE))
```

#### Arguments

- `bin` a numeric vector (of positive integers), or a factor. Long vectors are supported.
- `nbins` the number of bins to be used.

#### Details

`tabulate` is the workhorse for the `table` function.

If `bin` is a factor, its internal integer representation is tabulated.

If the elements of `bin` are numeric but not integers, they are truncated by `as.integer`.

#### Value

An integer valued integer or double vector (without names). There is a bin for each of the values 1, ..., `nbins`; values outside that range and NAs are (silently) ignored.

On 64-bit platforms `bin` can have $2^{31}$ or more elements (i.e., `length(bin) > .Machine$integer.max`), and hence a count could exceed the maximum integer. For this reason, the return value is of type double for such long `bin` vectors.

#### See Also

- `tabulate`, `factor`.
tapply

Apply a Function Over a Ragged Array

Description

Apply a function to each cell of a ragged array, that is to each (non-empty) group of values given by a unique combination of the levels of certain factors.

Usage

tapply(X, INDEX, FUN = NULL, ..., default = NA, simplify = TRUE)

Arguments

X an R object for which a split method exists. Typically vector-like, allowing subsetting with [.

INDEX a list of one or more factors, each of same length as X. The elements are coerced to factors by as.factor.

FUN a function (or name of a function) to be applied, or NULL. In the case of functions like +, %*%, etc., the function name must be backquoted or quoted. If FUN is NULL, tapply returns a vector which can be used to subscript the multi-way array tapply normally produces.

... optional arguments to FUN: the Note section.

default (only in the case of simplification to an array) the value with which the array is initialized as array(default, dim = ..). Before R 3.4.0, this was hard coded to array()’s default NA. If it is NA (the default), the missing value of the answer type, e.g. NA_real_, is chosen (as.raw(0) for "raw"). In a numerical case, it may be set, e.g., to FUN(integer(0)), e.g., in the case of FUN = sum to 0 or 0L.

simplify logical; if FALSE, tapply always returns an array of mode "list"; in other words, a list with a dim attribute. If TRUE (the default), then if FUN always returns a scalar, tapply returns an array with the mode of the scalar.

Details

If FUN is not NULL, it is passed to match.fun, and hence it can be a function or a symbol or character string naming a function.

Examples

tabulate(c(2,3,5))
tabulate(c(2,3,3,5), nbins = 10)
tabulate(c(-2,0,2,3,3,5)) # -2 and 0 are ignored
tabulate(c(-2,0,2,3,3,5), nbins = 3)
tabulate(factor(letters[1:10]))
Value

When FUN is present, tapply calls FUN for each cell that has any data in it. If FUN returns a single atomic value for each such cell (e.g., functions mean or var) and when simplify is TRUE, tapply returns a multi-way array containing the values, and NA for the empty cells. The array has the same number of dimensions as INDEX has components; the number of levels in a dimension is the number of levels (nlevels()) in the corresponding component of INDEX. Note that if the return value has a class (e.g., an object of class "Date") the class is discarded.

simplify = TRUE always returns an array, possibly 1-dimensional.

If FUN does not return a single atomic value, tapply returns an array of mode list whose components are the values of the individual calls to FUN, i.e., the result is a list with a dim attribute.

When there is an array answer, its dimnames are named by the names of INDEX and are based on the levels of the grouping factors (possibly after coercion).

For a list result, the elements corresponding to empty cells are NULL.

Note

Optional arguments to FUN supplied by the ... argument are not divided into cells. It is therefore inappropriate for FUN to expect additional arguments with the same length as X.

Examples

```
require(stats)
groups <- as.factor(rbinom(32, n = 5, prob = 0.4))
tapply(groups, groups, length) #- is almost the same as table(groups)

## contingency table from data.frame : array with named dimnames
tapply(warpbreaks$breaks, warpbreaks[, -1], sum)
tapply(warpbreaks$breaks, warpbreaks[, 3, drop = FALSE], sum)

n <- 17; fac <- factor(rep_len(1:3, n), levels = 1:5)
table(fac)
tapply(1:n, fac, sum)
tapply(1:n, fac, sum, default = 0) # maybe more desirable

tapply(1:n, fac, sum, simplify = FALSE)
tapply(1:n, fac, range)
tapply(1:n, fac, quantile)
tapply(1:n, fac, length) ## NA's
tapply(1:n, fac, length, default = 0) # == table(fac)

## example of ... argument: find quarterly means
tapply(presidents, cycle(presidents), mean, na.rm = TRUE)
```
ind <- list(c(1, 2, 2), c("A", "A", "B"))
table(ind)
tapply(1:3, ind) #-> the split vector
tapply(1:3, ind, sum)

## Some assertions (not held by all patch proposals):
q <- names(quantile(1:5))
stopifnot(
  identical(tapply(1:3, ind), c(1L, 2L, 4L)),
  identical(tapply(1:3, ind, sum),
    matrix(c(1L, 2L, NA, 3L), 2, dimnames = list(c("1", "2"), c("A", "B")))),
  identical(tapply(1:n, fac, quantile)[-1],
    array(list(2 = structure(c(2, 5.75, 9.5, 13.25, 17), .Names = q),
       3 = structure(c(3, 6, 9, 12, 15), .Names = q),
       4 = NULL, 5 = NULL), dim=4, dimnames=list(as.character(2:5)))))

---

**taskCallback**

*Add or Remove a Top-Level Task Callback*

**Description**

*addTaskCallback* registers an R function that is to be called each time a top-level task is completed.

*removeTaskCallback* un-registers a function that was registered earlier via *addTaskCallback*.

These provide low-level access to the internal/native mechanism for managing task-completion actions. One can use *taskCallbackManager* at the R-language level to manage R functions that are called at the completion of each task. This is easier and more direct.

**Usage**

```r
addTaskCallback(f, data = NULL, name = character())
removeTaskCallback(id)
```

**Arguments**

- **f**
  
  the function that is to be invoked each time a top-level task is successfully completed. This is called with 5 or 4 arguments depending on whether *data* is specified or not, respectively. The return value should be a logical value indicating whether to keep the callback in the list of active callbacks or discard it.

- **data**
  
  if specified, this is the 5-th argument in the call to the callback function *f*.

- **id**
  
  a string or an integer identifying the element in the internal callback list to be removed. Integer indices are 1-based, i.e. the first element is 1. The names of currently registered handlers is available using *getTaskCallbackNames* and is also returned in a call to *addTaskCallback*.

- **name**
  
  character: names to be used.

**Details**

Top-level tasks are individual expressions rather than entire lines of input. Thus an input line of the form `expression1 ; expression2` will give rise to 2 top-level tasks.

A top-level task callback is called with the expression for the top-level task, the result of the top-level task, a logical value indicating whether it was successfully completed or not (always TRUE at
present), and a logical value indicating whether the result was printed or not. If the data argument was specified in the call to `addTaskCallback`, that value is given as the fifth argument.

The callback function should return a logical value. If the value is FALSE, the callback is removed from the task list and will not be called again by this mechanism. If the function returns TRUE, it is kept in the list and will be called on the completion of the next top-level task.

**Value**

`addTaskCallback` returns an integer value giving the position in the list of task callbacks that this new callback occupies. This is only the current position of the callback. It can be used to remove the entry as long as no other values are removed from earlier positions in the list first.

`removeTaskCallback` returns a logical value indicating whether the specified element was removed. This can fail (i.e., return FALSE) if an incorrect name or index is given that does not correspond to the name or position of an element in the list.

**Note**

There is also C-level access to top-level task callbacks to allow C routines rather than R functions be used.

**See Also**

`getTaskCallbackNames`  `taskCallbackManager`  [https://developer.r-project.org/TaskHandlers.pdf](https://developer.r-project.org/TaskHandlers.pdf)

**Examples**

```r
# add the callback that will work for # 4 top-level tasks and then remove itself.
# addTaskCallback(times(4))
# now remove it, assuming it is still first in the list.
removeTaskCallback(n)

## See how the handler is called every time till "self destruction":
addTaskCallback(times(4)) # counts as once already
```

```r
sum(1:10); mean(1:3) # two more
sinpi(1) # 4th - and "done"
cospi(1)
```
taskCallbackManager

Create an R-level Task Callback Manager

Description
This provides an entirely R-language mechanism for managing callbacks or actions that are invoked at the conclusion of each top-level task. Essentially, we register a single R function from this manager with the underlying, native task-callback mechanism and this function handles invoking the other R callbacks under the control of the manager. The manager consists of a collection of functions that access shared variables to manage the list of user-level callbacks.

Usage

```r
taskCallbackManager(handlers = list(), registered = FALSE, verbose = FALSE)
```

Arguments

- **handlers**: this can be a list of callbacks in which each element is a list with an element named "f" which is a callback function, and an optional element named "data" which is the 5-th argument to be supplied to the callback when it is invoked. Typically this argument is not specified, and one uses add to register callbacks after the manager is created.

- **registered**: a logical value indicating whether the evaluate function has already been registered with the internal task callback mechanism. This is usually FALSE and the first time a callback is added via the add function, the evaluate function is automatically registered. One can control when the function is registered by specifying TRUE for this argument and calling addTaskCallback manually.

- **verbose**: a logical value, which if TRUE, causes information to be printed to the console about certain activities this dispatch manager performs. This is useful for debugging callbacks and the handler itself.

Value

A list containing 6 functions:

- **add()**: register a callback with this manager, giving the function, an optional 5-th argument, an optional name by which the callback is stored in the list, and a register argument which controls whether the evaluate function is registered with the internal C-level dispatch mechanism if necessary.

- **remove()**: remove an element from the manager’s collection of callbacks, either by name or position/index.

- **evaluate()**: the ‘real’ callback function that is registered with the C-level dispatch mechanism and which invokes each of the R-level callbacks within this manager’s control.

- **suspend()**: a function to set the suspend state of the manager. If it is suspended, none of the callbacks will be invoked when a task is completed. One sets the state by specifying a logical value for the status argument.
register() a function to register the evaluate function with the internal C-level dispatch mechanism. This is done automatically by the add function, but can be called manually.
callbacks() returns the list of callbacks being maintained by this manager.

Examples
# create the manager
h <- taskCallbackManager()

# add a callback
h$add(function(expr, value, ok, visible) {
cat("In handler\n")
return(TRUE)
}, name = "simpleHandler")

# look at the internal callbacks.
getTaskCallbackNames()

# look at the R-level callbacks
names(h$callbacks())

removeTaskCallback("R-taskCallbackManager")

---

**taskCallbackNames**

*Query the Names of the Current Internal Top-Level Task Callbacks*

**Description**

This provides a way to get the names (or identifiers) for the currently registered task callbacks that are invoked at the conclusion of each top-level task. These identifiers can be used to remove a callback.

**Usage**

getTaskCallbackNames()

**Value**

A character vector giving the name for each of the registered callbacks which are invoked when a top-level task is completed successfully. Each name is the one used when registering the callbacks and returned as the in the call to addTaskCallback.
Note

One can use `taskCallbackManager` to manage user-level task callbacks, i.e., S-language functions, entirely within the S language and access the names more directly.

Examples

```r
n <- addTaskCallback(function(expr, value, ok, visible) {
  cat("In handler\n")
  return(TRUE)
  }, name = "simpleHandler")

getTaskCallbackNames()

  # now remove it by name
removeTaskCallback("simpleHandler")

h <- taskCallbackManager()
h$add(function(expr, value, ok, visible) {
  cat("In handler\n")
  return(TRUE)
  }, name = "simpleHandler")

getTaskCallbackNames()
removeTaskCallback("R-taskCallbackManager")
```

---

tempfile

Create Names for Temporary Files

Description

`tempfile` returns a vector of character strings which can be used as names for temporary files.

Usage

```r
tempfile(pattern = "file", tmpdir = tempdir(), fileext = ")
tempdir(check = FALSE)
```

Arguments

- `pattern` a non-empty character vector giving the initial part of the name.
- `tmpdir` a non-empty character vector giving the directory name
- `fileext` a non-empty character vector giving the file extension
- `check` `logical` indicating if `tmpdir()` should be checked and recreated if no longer valid.
Details

The length of the result is the maximum of the lengths of the three arguments; values of shorter arguments are recycled.

The names are very likely to be unique among calls to tempfile in an R session and across simultaneous R sessions (unless tmpdir is specified). The filenames are guaranteed not to be currently in use.

The file name is made by concatenating the path given by tmpdir, the pattern string, a random string in hex and a suffix of fileext.

By default, tmpdir will be the directory given by tempdir(). This will be a subdirectory of the per-session temporary directory found by the following rule when the R session is started. The environment variables TMPDIR, TMP and TEMP are checked in turn and the first found which points to a writable directory is used: if none succeeds ‘/tmp’ is used. The path should not contain spaces.

Note that setting any of these environment variables in the R session has no effect on tempdir(): the per-session temporary directory is created before the interpreter is started.

Value

For tempfile a character vector giving the names of possible (temporary) files. Note that no files are generated by tempfile.

For tempdir, the path of the per-session temporary directory.

On Windows, both will use a backslash as the path separator.

On a Unix-alike, the value will be an absolute path (unless tmpdir is set to a relative path), but it need not be canonical (see normalizePath) and on macOS it often is not.

Note on parallel use

R processes forked by functions such as mclapply and makeForkCluster in package parallel share a per-session temporary directory. Further, the ‘guaranteed not to be currently in use’ applies only at the time of asking, and two children could ask simultaneously. This is circumvented by ensuring that tempfile calls in different children try different names.

Source

The final component of tempdir() is created by the POSIX system call mkdtemp, or if this is not available (e.g. on Windows) a version derived from the source code of GNU glibc.

It will be of the form ‘RtmpXXXXXX’ where the last 6 characters are replaced in a platform-specific way. POSIX only requires that the replacements be ASCII, which allows . (so the value may appear to have a file extension) and regexp metacharacters such as *. Most commonly the replacements are from the regexp pattern [A-Za-z0-9-], but has been seen.

unlink for deleting files.
Examples

```r
tempfile(c("ab", "a b c"))  # give file name with spaces in!
tempfile("plot", fileext = c(".ps", ".pdf"))
tempdir()  # works on all platforms with a platform-dependent result

## Show how 'check' is working on some platforms:
if(exists("I'm brave") && 'I'm brave' &&
   identical(.Platform$OS.type, "unix") && grepl("/tmp/", tempdir())) {
  cat("Current tempdir(): ", tempdir(), \\n"
  cat("Removing it ":, file.remove(tempdir()),
    "; dir.exists(tempdir())":, dir.exists(tempdir()), "\\n"
  cat("and now tempdir(check = TRUE): ", tempdir(check = TRUE),"\\n")
}
```

---

**textConnection**  

**Text Connections**

---

**Description**

Input and output text connections.

**Usage**

```r
textConnection(object, open = "r", local = FALSE,
  name = deparse(substitute(object)),
  encoding = c("", "bytes", "UTF-8"))
```

```r
textConnectionValue(con)
```

**Arguments**

- `object` character. A description of the connection. For an input this is an **R** character vector object, and for an output connection the name for the **R** character vector to receive the output, or **NULL** (for none).
- `open` character string. Either "r" (or equivalently "") for an input connection or "w" or "a" for an output connection.
- `local` logical. Used only for output connections. If **TRUE**, output is assigned to a variable in the calling environment. Otherwise the global environment is used.
- `name` a **character** string specifying the connection name.
- `encoding` character string, partially matched. Used only for input connections. How marked strings in object should be handled: converted to the current locale, used byte-by-byte or translated to UTF-8.
- `con` An output text connection.
Details

An input text connection is opened and the character vector is copied at time the connection object is created, and \texttt{close} destroys the copy. \texttt{object} should be the name of a character vector: however, short expressions will be accepted provided they \texttt{deparse} to less than 60 bytes.

An output text connection is opened and creates an \texttt{R} character vector of the given name in the user’s workspace or in the calling environment, depending on the value of the \texttt{local} argument. This object will at all times hold the completed lines of output to the connection, and \texttt{isIncomplete} will indicate if there is an incomplete final line. Closing the connection will output the final line, complete or not. (A line is complete once it has been terminated by end-of-line, represented by “\texttt{\textbackslash n}” in \texttt{R}.) The output character vector has locked bindings (see \texttt{lockBinding}) until \texttt{close} is called on the connection. The character vector can also be retrieved via \texttt{textConnectionValue}, which is the only way to do so if \texttt{object = NULL}. If the current locale is detected as Latin-1 or UTF-8, non-ASCII elements of the character vector will be marked accordingly (see \texttt{Encoding}).

Opening a text connection with \texttt{mode = "a"} will attempt to append to an existing character vector with the given name in the user’s workspace or the calling environment. If none is found (even if an object exists of the right name but the wrong type) a new character vector will be created, with a warning.

You cannot \texttt{seek} on a text connection, and \texttt{seek} will always return zero as the position.

Text connections have slightly unusual semantics: they are always open, and throwing away an input text connection without closing it (so it get garbage-collected) does not give a warning.

Value

For \texttt{textConnection}, a connection object of class "textConnection" which inherits from class "connection".

For \texttt{textConnectionValue}, a character vector.

Note

As output text connections keep the character vector up to date line-by-line, they are relatively expensive to use, and it is often better to use an anonymous \texttt{file()} connection to collect output.

On (rare) platforms where \texttt{vsnprintf} does not return the needed length of output there is a 100,000 character limit on the length of line for output connections: longer lines will be truncated with a warning.

summary(resid(lm.D9))
sink()
close(zz)
cat(foo, sep = "\n")

tilde

Tilde Operator

Description

Tilde is used to separate the left- and right-hand sides in a model formula.

Usage

y ~ model

Arguments

y, model symbolic expressions.

Details

The left-hand side is optional, and one-sided formulae are used in some contexts.
A formula has mode call. It can be subsetted by [[]: the components are ~, the left-hand side (if present) and the right-hand side in that order.

formula
Description

Information about time zones in R. `Sys.timezone` returns the name of the current time zone.

Usage

```r
Sys.timezone(location = TRUE)
OlsonNames(tzdir = NULL)
```

Arguments

- `location` logical: defunct: ignored, with a warning for false values.
- `tzdir` The time-zone database to be used: the default is to try known locations until one is found.

Details

Time zones are a system-specific topic, but these days almost all R platforms use similar underlying code, used by Linux, macOS, Solaris, AIX and FreeBSD, and installed with R on Windows. (Unfortunately there are many system-specific errors in the implementations.) It is possible to use the R sources’ version of the code on Unix-alikes as well as on Windows: this is the default for macOS and recommended for Solaris.

It should be possible to set the current time zone via the environment variable `TZ`: see the section on ‘Time zone names’ for suitable values. `Sys.timezone()` will return the value of `TZ` if set initially (and on some OSes it is always set), otherwise it will try to retrieve from the OS a value which if set for `TZ` would give the initial time zone. (‘Initially’ means before any time-zone functions are used: if `TZ` is being set to override the OS setting or if the ‘try’ does not get this right, it should be set before the R process is started or (probably early enough) in file `.Rprofile`.

If `TZ` is set but invalid, most platforms default to ‘UTC’, the time zone colloquially known as ‘GMT’ (see https://en.wikipedia.org/wiki/Coordinated_Universal_Time). (Some but not all platforms will give a warning for invalid values.) If it is unset or empty the system time zone is used (the one returned by `Sys.timezone`).

Time zones did not come into use until the middle of the nineteenth century and were not widely adopted until the twentieth, and *daylight saving time* (DST, also known as *summer time*) was first introduced in the early twentieth century, most widely in 1916. Over the last 100 years places have changed their affiliation between major time zones, have opted out of (or in to) DST in various years or adopted DST rule changes late or not at all. (The UK experimented with DST throughout 1971, only.) In a few countries (one is the Irish Republic) it is the summer time which is the ‘standard’ time and a different name is used in winter. And there can be multiple changes during a year, for example for Ramadan.

A quite common system implementation of POSIXct is as signed 32-bit integers and so only goes back to the end of 1901: on such systems R assumes that dates prior to that are in the same time zone as they were in 1902. Most of the world had not adopted time zones by 1902 (so used local ‘mean time’ based on longitude) but for a few places there had been time-zone changes before then. 64-bit representations are becoming common; unfortunately on some 64-bit OSes the database
information is 32-bit and so only available for the range 1901–2038, and incompletely for the end years.

As from R 3.5.0, when a time zone location is first found in a session, its value is cached in object .sys.timezone in the base environment.

Value

Sys.timezone returns an OS-specific character string, possibly NA or an empty string (which on some OSes means 'UTC'). This will be a location such as "Europe/London" if one can be ascertained.

A time zone region may be known by several names: for example "Europe/London" is also known as 'GB', 'GB=Eire', 'Europe/Belfast', 'Europe/Guernsey', 'Europe/Isle_of_Man' and 'Europe/Jersey'. A few regions are also known by a summary of their time zone, e.g. 'PST8PDT' is an alias for 'America/Los_Angeles'.

OlsonNames returns a character vector, see the examples for typical cases. It may have an attribute "Version", something like "2020a".

Time zone names

Names "UTC" and its synonym "GMT" are accepted on all platforms.

Where OSes describe their valid time zones can be obscure. The help for the C function tzset can be helpful, but it can also be inaccurate. There is a cumbersome POSIX specification (listed under environment variable TZ at https://pubs.opengroup.org/onlinepubs/9699917999/basedefs/V1_chap08.html#tag_08), which is often at least partially supported, but there are other more user-friendly ways to specify time zones.

Almost all R platforms make use of a time-zone database originally compiled by Arthur David Olson and now managed by IANA, in which the preferred way to refer to a time zone is by a location (typically of a city), e.g., Europe/London, America/Los_Angeles, Pacific/Easter within a 'time zone region'. Some traditional designations are also allowed such as EST5EDT or GB. (Beware that some of these designations may not be what you expect: in particular EST is a time zone used in Canada without daylight saving time, and not EST5EDT nor (Australian) Eastern Standard Time.)

The designation can also be an optional colon prepended to the path to a file giving compiled zone information (and the examples above are all files in a system-specific location). See https://data.iana.org/time-zones/tz-link.html for more details and references. By convention, regions with a unique time-zone history since 1970 have specific names in the database, but those with different earlier histories may not. Each time zone has one or two (the second for DST) abbreviations used when formatting times.

The abbreviations used have changed over the years: for example France used ‘PMT’ (‘Paris Mean Time’) from 1891 to 1911 then ‘WET/WEST’ up to 1940 and ‘CET/CEST’ from 1946. (In almost all time zones the abbreviations have been stable since 1970.) The POSIX standard allows only one or two abbreviations per time zone, so you may see the current abbreviation(s) used for older times.

For some time zones abbreviations are like ‘-03’ and ‘+0845’: this is done when there is no official abbreviation. (Negative values are behind (West of) UTC, as for the "%z" format for strftime.)

The function OlsonNames returns the time-zone names known to the currently selected Olson/IANA database. The system-specific location in the file system varies, e.g. ‘/usr/share/zoneinfo’ (Linux, macOS, FreeBSD), ‘/usr/share/lib/zoneinfo’ (Solaris, AIX), .... It is likely that there is a file named something like ‘zone1970.tab’ or (older) ‘zone.tab’ under that directory listing the locations known as time-zone names (but not for example EST5EDT). See also https://en.wikipedia.org/wiki/Zone.tab.
Where \texttt{R} was configured with option ‘--with-internal-tzcode’ (the default on Windows: recommended on Solaris), the database at \texttt{R.home("share")/"zoneinfo"} is used by default: file ‘VERSION’ in that directory states the version. That option is also the default on macOS but there whichever is more recent of the system database at ‘/var/db/timezone/zoneinfo’ and that distributed with \texttt{R} is used by default. Environment variable \texttt{TZDIR} can be used to point to a different ‘zoneinfo’ database: value "internal" indicates that the database from the \texttt{R} sources and "macOS" indicates the system database.

Setting \texttt{TZDIR} is also supported by the native services on some OSes, e.g. Linux using \texttt{glibc} except in secure modes.

Time zones given by name (via environment variable \texttt{TZ}, in \texttt{tz} arguments to functions such as \texttt{as.POSIXlt} and perhaps the system time zone) are loaded from the currently selected ‘zoneinfo’ database.

Most platforms support time zones of the form ‘Etc/GMT+n’ and ‘Etc/GMT-n’ (possibly without prefix ‘Etc/’), which assume a fixed offset from UTC (hence no DST). Contrary to some expectations (but consistent with names such as ‘PST8PDT’), negative offsets are times ahead of (east of) UTC, positive offsets are times behind (west of) UTC.

Immediately prior to the advent of legislated time zones, most people used time based on their longitude (or that of a nearby town), known as ‘Local Mean Time’ and abbreviated as ‘LMT’ in the databases: in many countries that was codified with a specific name before the switch to a standard time. For example, Paris codified its LMT as ‘Paris Mean Time’ in 1891 (to be used throughout mainland France) and switched to ‘GMT+0’ in 1911.

Some systems (notably Linux) have a \texttt{tzselect} command which allows the interactive selection of a supported time zone name. On systems using \texttt{systemd} (notably Linux), the OS command \texttt{timedatectl list-timezones} will list all available time zone names.

**Warning**

There is a system-specific upper limit on the number of bytes in (abbreviated) time-zone names which can be as low as 6 (as required by POSIX). Some OSes allow the setting of time zones with names which exceed their limit, and that can crash the \texttt{R} session.

\texttt{OlsonNames} tries to find an Olson database in known locations. It might not succeed (when it returns an empty vector with a warning) and even if it does it might not locate the database used by the date-time code linked into \texttt{R}. Fortunately names are added rarely and most databases are pretty complete.

**How the system time zone is found**

This section is of background interest for users of a Unix-alike, but may help if an \texttt{NA} value is returned unexpectedly.

Commercial Unixen such as Solaris and AIX set \texttt{TZ}, so the value when \texttt{R} is started is used.

All other common platforms (Linux, macOS, *BSD) use similar schemes, either derived from \texttt{tzcode} (currently distributed from \url{https://www.iana.org/time-zones}) or independently coded (glibc, musl-libc). Such systems read the time-zone information from a file ‘localtime’, usually under ‘/etc’ (but possibly under ‘/usr/local/etc’ or ‘/usr/local/etc/zoneinfo’). As the usual Linux manual page for \texttt{localtime} says

‘Because the time zone identifier is extracted from the symlink target name of ‘/etc/localtime’, this file may not be a normal file or hardlink.’

Nevertheless, some Linux distributions (including the one from which that quote was taken) or sysadmins have chosen to copy a time-zone file to ‘localtime’. For a non-symlink, the ultimate fallback is to compare that file to all files in the time-zone database.
Some Linux platforms provide two other mechanisms which are tried in turn before looking at `/etc/localtime`.

- ‘Modern’ Linux systems use systemd which provides mechanisms to set and retrieve the time zone (amongst other things). There is a command `timedatectl` to give details. (Unfortunately RHEL/Centos 6.x are not ‘modern’).
- Debian-derived systems since ca 2007 have supplied a file `/etc/timezone`. Its format is undocumented but empirically it contains a single line of text naming the time zone.

In each case a sanity check is performed that the time-zone name is the name of a file in the time-zone database. (The systems probably use the time-zone file (symlinked to) `/etc/localtime`, but the `Sys.timezone` code does not check that is the same as the named file in the database. This is deliberate as they may be from different dates.)

**Note**

Since 2007 there has been considerable disruption over changes to the timings of the DST transitions, originally aimed at energy conservation. These often have short notice and time-zone databases may not be up to date. (Morocco in 2013 announced a change to the end of DST at a days notice, and in 2015 North Korea gave imprecise information about a change a week in advance.)

On platforms with case-insensitive file systems, time zone names will be case-insensitive. They may or may not be on other platforms and so, for example, "gmt" is valid on some platforms and not on others.

Note that except where replaced, the operation of time zones is an OS service, and even where replaced a third-party database is used and can be updated (see the section on ‘Time zone names’). Incorrect results will never be an R issue, so please ensure that you have the courtesy not to blame R for them.

**Examples**

```
Sys.timezone()
```

```
str(OlsonNames()) # typically close to 600 hundred names,
# typically some acronyms/aliases such as "UTC", "NZ", "MET", "Eire", ..., but
# mostly pairs (and triplets) such as "Pacific/Auckland"
table(sl <- grepl("/", OlsonNames()))
OlsonNames()[!sl] # the simple ones
head(Osl <- strsplit(OlsonNames()[sl], "/"))
(tOsl <- table(vapply(Osl, "+", 1))) # Continents, countries, ...
table(lengths(Osl)) # most are pairs, some triplets
str(Osl[lengths(Osl) >= 3]) # "America" South and North ...
```
toString

Convert an R Object to a Character String

Description

This is a helper function for `format` to produce a single character string describing an R object.

Usage

```r
toString(x, ...)
```

## Default S3 method:
```r
toString(x, width = NULL, ...)
```

Arguments

- `x` The object to be converted.
- `width` Suggestion for the maximum field width. Values of NULL or 0 indicate no maximum. The minimum value accepted is 6 and smaller values are taken as 6.
- `...` Optional arguments passed to or from methods.

Details

This is a generic function for which methods can be written: only the default method is described here. Most methods should honor the `width` argument to specify the maximum display width (as measured by `nchar(type = "width")`) of the result.

The default method first converts `x` to character and then concatenates the elements separated by ",". If `width` is supplied and is not NULL, the default method returns the first `width - 4` characters of the result with `...` appended, if the full result would use more than `width` characters.

Value

A character vector of length 1 is returned.

x <- c("a", "b", "aaaaaaaaaa")
toString(x)
toString(x, width = 8)
```
Interactive Tracing and Debugging of Calls to a Function or Method

Description
A call to trace allows you to insert debugging code (e.g., a call to browser or recover) at chosen places in any function. A call to untrace cancels the tracing. Specified methods can be traced the same way, without tracing all calls to the generic function. Trace code (tracer) can be any R expression. Tracing can be temporarily turned on or off globally by calling tracingState.

Usage

```r
trace(what, tracer, exit, at, print, signature,
      where = topenv(parent.frame()), edit = FALSE)
untrace(what, signature = NULL, where = topenv(parent.frame()))
tracingState(on = NULL)
.doTrace(expr, msg)
.returnValue(default = NULL)
```

Arguments

- `what` the name, possibly `quote()`d, of a function to be traced or untraced. For untrace or for trace with more than one argument, more than one name can be given in the quoted form, and the same action will be applied to each one. For “hidden” functions such as S3 methods in a namespace, `where = *` typically needs to be specified as well.

- `tracer` either a function or an unevaluated expression. The function will be called or the expression will be evaluated either at the beginning of the call, or before those steps in the call specified by the argument `at`. See the details section.

- `exit` either a function or an unevaluated expression. The function will be called or the expression will be evaluated on exiting the function. See the details section.

- `at` optional numeric vector or list. If supplied, `tracer` will be called just before the corresponding step in the body of the function. See the details section.

- `print` If `TRUE` (as per default), a descriptive line is printed before any trace expression is evaluated.

- `signature` If this argument is supplied, it should be a signature for a method for function `what`. In this case, the method, and not the function itself, is traced.

- `edit` For complicated tracing, such as tracing within a loop inside the function, you will need to insert the desired calls by editing the body of the function. If so, supply the `edit` argument either as `TRUE`, or as the name of the editor you want to use. Then `trace()` will call `edit` and use the version of the function after you edit it. See the details section for additional information.

- `where` where to look for the function to be traced; by default, the top-level environment of the call to trace.

An important use of this argument is to trace functions from a package which are “hidden” or called from another package. The namespace mechanism imports the functions to be called (with the exception of functions in the base package). The functions being called are `not` the same objects seen from the top-level (in
general, the imported packages may not even be attached). Therefore, you must ensure that the correct versions are being traced. The way to do this is to set argument where to a function in the namespace (or that namespace). The tracing computations will then start looking in the environment of that function (which will be the namespace of the corresponding package). (Yes, it’s subtle, but the semantics here are central to how namespaces work in R.)

on logical; a call to the support function tracingState returns TRUE if tracing is globally turned on, FALSE otherwise. An argument of one or the other of those values sets the state. If the tracing state is FALSE, none of the trace actions will actually occur (used, for example, by debugging functions to shut off tracing during debugging).

expr, msg arguments to the support function .doTrace, calls to which are inserted into the modified function or method: expr is the tracing action (such as a call to browser()), and msg is a string identifying the place where the trace action occurs.

default If returnValue finds no return value (e.g. a function exited because of an error, restart or as a result of evaluating a return from a caller function), it will return default instead.

Details

The trace function operates by constructing a revised version of the function (or of the method, if signature is supplied), and assigning the new object back where the original was found. If only the what argument is given, a line of trace printing is produced for each call to the function (back compatible with the earlier version of trace).

The object constructed by trace is from a class that extends "function" and which contains the original, untraced version. A call to untrace re-assigns this version.

If the argument tracer or exit is the name of a function, the tracing expression will be a call to that function, with no arguments. This is the easiest and most common case, with the functions browser and recover the likeliest candidates; the former browses in the frame of the function being traced, and the latter allows browsing in any of the currently active calls. The arguments tracer and exit are evaluated to see whether they are functions, but only their names are used in the tracing expressions. The lookup is done again when the traced function executes, so it may not be tracer or exit that will be called while tracing.

The tracer or exit argument can also be an unevaluated expression (such as returned by a call to quote or substitute). This expression itself is inserted in the traced function, so it will typically involve arguments or local objects in the traced function. An expression of this form is useful if you only want to interact when certain conditions apply (and in this case you probably want to supply print = FALSE in the call to trace also).

When the at argument is supplied, it can be a vector of integers referring to the substeps of the body of the function (this only works if the body of the function is enclosed in { ...}). In this case tracer is not called on entry, but instead just before evaluating each of the steps listed in at. (Hint: you don’t want to try to count the steps in the printed version of a function; instead, look at as.list(body(f)) to get the numbers associated with the steps in function f.)

The at argument can also be a list of integer vectors. In this case, each vector refers to a step nested within another step of the function. For example, at = list(c(3,4)) will call the tracer just before the fourth step of the third step of the function. See the example below.

Using setBreakpoint (from package utils) may be an alternative, calling trace(....,at,...).
The `exit` argument is called during `on.exit` processing. In an `on.exit` expression, the experimental `returnValue()` function may be called to obtain the value about to be returned by the function. Calling this function in other circumstances will give undefined results.

An intrinsic limitation in the `exit` argument is that it won’t work if the function itself uses `on.exit` with `add=FALSE` (the default), since the existing calls will override the one supplied by `trace`.

Tracing does not nest. Any call to `trace` replaces previously traced versions of that function or method (except for edited versions as discussed below), and `untrace` always restores an untraced version. (Allowing nested tracing has too many potentials for confusion and for accidentally leaving traced versions behind.)

When the `edit` argument is used repeatedly with no call to `untrace` on the same function or method in between, the previously edited version is retained. If you want to throw away all the previous tracing and then edit, call `untrace` before the next call to `trace`. Editing may be combined with automatic tracing; just supply the other arguments such as `tracer`, and the `edit` argument as well.

The `edit = TRUE` argument uses the default editor (see `edit`).

Tracing primitive functions (builts and specials) from the base package works, but only by a special mechanism and not very informatively. Tracing a primitive causes the primitive to be replaced by a function with argument ... (only). You can get a bit of information out, but not much. A warning message is issued when `trace` is used on a primitive.

The practice of saving the traced version of the function back where the function came from means that tracing carries over from one session to another, if the traced function is saved in the session image. (In the next session, `untrace` will remove the tracing.) On the other hand, functions that were in a package, not in the global environment, are not saved in the image, so tracing expires with the session for such functions.

Tracing an S4 method is basically just like tracing a function, with the exception that the traced version is stored by a call to `setMethod` rather than by direct assignment, and so is the untraced version after a call to `untrace`.

The version of `trace` described here is largely compatible with the version in S-Plus, although the two work by entirely different mechanisms. The S-Plus `trace` uses the session frame, with the result that tracing never carries over from one session to another (R does not have a session frame). Another relevant distinction has nothing directly to do with `trace`: The browser in S-Plus allows changes to be made to the frame being browsed, and the changes will persist after exiting the browser. The R browser allows changes, but they disappear when the browser exits. This may be relevant in that the S-Plus version allows you to experiment with code changes interactively, but the R version does not. (A future revision may include a ‘destructive’ browser for R.)

**Value**

In the simple version (just the first argument), `trace` returns an invisible `NULL`. Otherwise, the traced function(s) name(s). The relevant consequence is the assignment that takes place.

`untrace` returns the function name invisibly.

`tracingState` returns the current global tracing state, and possibly changes it.

When called during `on.exit` processing, `returnValue` returns the value about to be returned by the exiting function. Behaviour in other circumstances is undefined.

**Note**

Using `trace()` is conceptually a generalization of `debug`, implemented differently. Namely by calling `browser` via its `tracer` or `exit` argument.
The version of function tracing that includes any of the arguments except for the function name requires the methods package (because it uses special classes of objects to store and restore versions of the traced functions).

If methods dispatch is not currently on, trace will load the methods namespace, but will not put the methods package on the search list.

browser and recover, the likeliest tracing functions; also, quote and substitute for constructing general expressions.

Examples

```
require(stats)

## Very simple use
trace(sum)
hist(rnorm(100)) # shows about 3-4 calls to sum()
untrace(sum)

## Show how pt() is called from inside power.t.test():
if(FALSE)
  trace(pt) ## would show ~20 calls, but we want to see more:
  tracer = quote(cat(sprintf("tracing pt(*, ncp = %.15g)\n", ncp))),
  print = FALSE) # <- not showing typical extra
power.t.test(20, 1, power=0.8, sd=NULL) #--> showing the ncp root finding:
untrace(pt)

f <- function(x, y) {
  y <- pmax(y, 0.001)
  if (x > 0) x ^ y else stop("x must be positive")
}

## arrange to call the browser on entering and exiting
## function f
trace("f", quote(browser(skipCalls = 4)),
  exit = quote(browser(skipCalls = 4)))

## instead, conditionally assign some data, and then browse
## on exit, but only then. Don't bother me otherwise
trace("f", quote(if(any(y < 0)) yOrig <- y),
  exit = quote(if(exists("yOrig")) browser(skipCalls = 4)),
  print = FALSE)

## Enter the browser just before stop() is called. First, find
## the step numbers
untrace(f) # (as it has changed f's body !)
```
as.list(body(f))
as.list(body(f)[[3]]) # -> stop(..) is [[4]]

## Now call the browser there

trace("f", quote(browser(skipCalls = 4)), at = list(c(3,4)))
## Not run:
f(-1,2) # --> enters browser just before stop(..)
## End(Not run)

## trace a utility function, with recover so we
## can browse in the calling functions as well.

trace("as.matrix", recover)

## turn off the tracing (that happened above)

untrace(c("f", "as.matrix"))

## Not run:
## Useful to find how system2() is called in a higher-up function:
trace(base::system2, quote(print(ls.str())))

## End(Not run)

##-------- Tracing hidden functions : need 'where = *'
##
## 'where' can be a function whose environment is meant:
trace(quote(ar.yw.default), where = ar)
a <- ar(rnorm(100)) # "Tracing ..."
untrace(quote(ar.yw.default), where = ar)

## trace() more than one function simultaneously:
## expression(E1, E2, ...) here is equivalent to
## c(quote(E1), quote(E2), quote(.*)...)
trace(expression(ar.yw, ar.yw.default), where = ar)
a <- ar(rnorm(100)) # --> 2 x "Tracing ..."
# and turn it off:
untrace(expression(ar.yw, ar.yw.default), where = ar)

## Not run:
## trace calls to the function lm() that come from
## the nlme package.
## (The function nlme is in that package, and the package
## has a namespace, so the where= argument must be used
## to get the right version of lm)

trace(lm, exit = recover, where = asNamespace("nlme"))

## End(Not run)
Description

By default traceback() prints the call stack of the last uncaught error, i.e., the sequence of calls that lead to the error. This is useful when an error occurs with an unidentifiable error message. It can also be used to print the current stack or arbitrary lists of calls.

.traceback() now returns the above call stack (and traceback(x,*) can be regarded as convenience function for printing the result of .traceback(x)).

Usage

```
traceback(x = NULL, max.lines = getOption("traceback.max.lines", 
    getOption("deparse.max.lines", -1L)))
```

Arguments

- **x** NULL (default, meaning .Traceback), or an integer count of calls to skip in the current stack, or a list or pairlist of calls. See the details.
- **max.lines** a number, the maximum number of lines to be printed per call. The default is unlimited. Applies only when x is NULL, a list or a pairlist of calls, see the details.

Details

The default display is of the stack of the last uncaught error as stored as a list of calls in .Traceback, which traceback prints in a user-friendly format. The stack of calls always contains all function calls and all foreign function calls (such as .Call): if profiling is in progress it will include calls to some primitive functions. (Calls to builtins are included, but not to specials.) Errors which are caught via try or tryCatch do not generate a traceback, so what is printed is the call sequence for the last uncaught error, and not necessarily for the last error.

If x is numeric, then the current stack is printed, skipping x entries at the top of the stack. For example, options(error = function() traceback(3)) will print the stack at the time of the error, skipping the call to traceback() and .traceback() and the error function that called it.

Otherwise, x is assumed to be a list or pairlist of calls or deparsed calls and will be displayed in the same way.

.traceback() and by extension traceback() may trigger deparsing of calls. This is an expensive operation for large calls so it may be advisable to set max.lines to a reasonable value when such calls are on the call stack.

Value

.traceback() returns the deparsed call stack deepest call first as a list or pairlist. The number of lines deparsed from the call can be limited via max.lines. Calls for which max.lines results in truncated output will gain a "truncated" attribute.

traceback() formats, prints, and returns the call stack produced by .traceback() invisibly.

Warning

It is undocumented where .Traceback is stored nor that it is visible, and this is subject to change. As of R 4.0.0 .Traceback contains the calls as language objects, whereas previously these calls were deparsed.
tracemem

References

Examples

```r
foo <- function(x) { print(1); bar(2) }
bar <- function(x) { x + a.variable.which.does.not.exist }
## Not run:
foo(2) # gives a strange error
traceback()
## End(Not run)
## 2: bar(2)
## 1: foo(2)
bar
## Ah, this is the culprit ...
## This will print the stack trace at the time of the error.
options(error = function() traceback(3))
```

---

tracemem Trace Copying of Objects

Description

This function marks an object so that a message is printed whenever the internal code copies the object. It is a major cause of hard-to-predict memory use in R.

Usage

```r
tracemem(x)
untracemem(x)
retracemem(x, previous = NULL)
```

Arguments

- `x` An R object, not a function or environment or NULL.
- `previous` A value as returned by tracemem or retracemem.

Details

This functionality is optional, determined at compilation, because it makes R run a little more slowly even when no objects are being traced. tracemem and untracemem give errors when R is not compiled with memory profiling; retracemem does not (so it can be left in code during development).

It is enabled in the CRAN macOS and Windows builds of R.

When an object is traced any copying of the object by the C function duplicate produces a message to standard output, as does type coercion and copying when passing arguments to .C or .Fortran.

The message consists of the string tracemem, the identifying strings for the object being copied and the new object being created, and a stack trace showing where the duplication occurred.
retracemem() is used to indicate that a variable should be considered a copy of a previous variable (e.g., after subscripting).

The messages can be turned off with tracingState.

It is not possible to trace functions, as this would conflict with trace and it is not useful to trace NULL, environments, promises, weak references, or external pointer objects, as these are not duplicated.

These functions are primitive.

Value

A character string for identifying the object in the trace output (an address in hex enclosed in angle brackets), or NULL (invisibly).

See Also

capabilities("profmem") to see if this was enabled for this build of R.

trace, Rprofmem

https://developer.r-project.org/memory-profiling.html

Examples

## Not run:
a <- 1:10
tracemem(a)
## b and a share memory
b <- a
b[1] <- 1
untracemem(a)

## copying in lm: less than R <= 2.15.0
d <- stats::rnorm(10)
tracemem(d)
lm(d ~ a+log(b))

## f is not a copy and is not traced
f <- d[-1]
f+1
## indicate that f should be traced as a copy of d
retracemem(f, retracemem(d))
f+1

## End(Not run)

---

**transform**

Transform an Object, for Example a Data Frame

Description

transform is a generic function, which—at least currently—only does anything useful with data frames. transform.default converts its first argument to a data frame if possible and calls transform.data.frame.
transform

Usage

transform(`_data`, ...) 

Arguments

_data  The object to be transformed
...
Further arguments of the form tag=value

Details

The ... arguments to transform.data.frame are tagged vector expressions, which are evaluated in the data frame _data. The tags are matched against names(_data), and for those that match, the value replace the corresponding variable in _data, and the others are appended to _data.

Value

The modified value of _data.

Warning

This is a convenience function intended for use interactively. For programming it is better to use the standard subsetting arithmetic functions, and in particular the non-standard evaluation of argument transform can have unanticipated consequences.

Note

If some of the values are not vectors of the appropriate length, you deserve whatever you get!

transform(airquality, new = ~Ozone, Temp = (Temp-32)/1.8)
attach(airquality)
transform(Ozone, logOzone = log(Ozone)) # marginally interesting ...
detach(airquality)
Trig

Trigonometric Functions

Description

These functions give the obvious trigonometric functions. They respectively compute the cosine, sine, tangent, arc-cosine, arc-sine, arc-tangent, and the two-argument arc-tangent.

\[ \cos(x), \sin(x), \text{ and } \tan(x), \text{ compute } \cos(\pi x), \sin(\pi x), \text{ and } \tan(\pi x). \]

Usage

\[ \cos(x), \sin(x), \tan(x) \]
\[ \acos(x), \asin(x), \atan(x) \]
\[ \atan2(y, x) \]
\[ \cospi(x), \sinpi(x), \text{ and } \tanpi(x) \]

Arguments

\[ x, y \] numeric or complex vectors.

Details

The arc-tangent of two arguments \( \atan2(y, x) \) returns the angle between the x-axis and the vector from the origin to \( (x, y) \), i.e., for positive arguments \( \atan2(y, x) = \atan(y/x) \).

Angles are in radians, not degrees, for the standard versions (i.e., a right angle is \( \pi/2 \)), and in 'half-rotations' for \( \cospi \) etc.

\( \cospi(x), \sinpi(x), \text{ and } \tanpi(x) \) are accurate for \( x \) values which are multiples of a half.

All except \( \atan2 \) are internal generic primitive functions: methods can be defined for them individually or via the \texttt{Math} group generic.

These are all wrappers to system calls of the same name (with prefix \texttt{c} for complex arguments) where available. (\( \cospi, \sinpi, \text{ and } \tanpi \) are part of a C11 extension and provided by e.g. macOS and Solaris: where not yet available call to \( \cos \) etc are used, with special cases for multiples of a half.)

Value

\( \tanpi(0.5) \) is \texttt{NaN}. Similarly for other inputs with fractional part \( 0.5 \).
Complex values

For the inverse trigonometric functions, branch cuts are defined as in Abramowitz and Stegun, figure 4.4, page 79.

For \( \text{asin} \) and \( \text{acos} \), there are two cuts, both along the real axis: \((-\infty, -1] \) and \([1, \infty)\).

For \( \text{atan} \) there are two cuts, both along the pure imaginary axis: \((-\infty i, -1i] \) and \([1i, \infty i)\).

The behaviour actually on the cuts follows the C99 standard which requires continuity coming round the endpoint in a counter-clockwise direction.

Complex arguments for \( \text{cospi} \), \( \text{sinpi} \), and \( \text{tanpi} \) are not yet implemented, and they are a ‘future direction’ of ISO/IEC TS 18661-4.

S4 methods

All except \( \text{atan2} \) are S4 generic functions: methods can be defined for them individually or via the \texttt{Math} group generic.

Chapter 4. Elementary Transcendental Functions: Logarithmic, Exponential, Circular and Hyperbolic Functions

For \( \text{cospi} \), \( \text{sinpi} \), and \( \text{tanpi} \) the C11 extension ISO/IEC TS 18661-4:2015 (draft at http://www.open-std.org/jtc1/sc22/wg14/www/docs/n1950.pdf).

Examples

```r
x <- seq(-3, 7, by = 1/8)
x <- cbind(x, cos(pi*x), cospi(x), sin(pi*x), sinpi(x),
          tan(pi*x), tanpi(x), deparse.level=2)
op <- options(digits = 4, width = 90) # for nice formatting
head(tx)
```

```r
options(op)
```

trimws

\textit{Remove Leading/Trailing Whitespace}

\textbf{Description}

Remove leading and/or trailing whitespace from character strings.

\textbf{Usage}

\begin{verbatim}
trimws(x, which = c("both", "left", "right"), whitespace = \"[ \t\r\n\"]\")
\end{verbatim}
try

Try an Expression Allowing Error Recovery

Description

try is a wrapper to run an expression that might fail and allow the user's code to handle error-recovery.

Usage

try(expr, silent = FALSE, outFile = getOption("try.outFile", default = stderr()))

Arguments

- expr: an R expression to try.
- silent: logical: should the report of error messages be suppressed?
- outFile: a connection, or a character string naming the file to print to (via cat(*, file = outFile)); used only if silent is false, as by default.
**Details**

try evaluates an expression and traps any errors that occur during the evaluation. If an error occurs then the error message is printed to the stderr connection unless options("show.error.messages") is false or the call includes silent = TRUE. The error message is also stored in a buffer where it can be retrieved by geterrmessage. (This should not be needed as the value returned in case of an error contains the error message.)

try is implemented using tryCatch; for programming, instead of try(expr,silent = TRUE), something like tryCatch(expr,error = function(e) e) (or other simple error handler functions) may be more efficient and flexible.

It may be useful to set the default for outFile to stdout(), i.e.,

    options(try.outFile = stdout())

instead of the default stderr(), notably when try() is used inside a Sweave code chunk and the error message should appear in the resulting document.

**Value**

The value of the expression if expr is evaluated without error, but an invisible object of class "try-error" containing the error message, and the error condition as the "condition" attribute, if it fails.

**See Also**

options for setting error handlers and suppressing the printing of error messages; geterrmessage for retrieving the last error message. The underlying tryCatch provides more flexible means of catching and handling errors.

assertCondition in package tools is related and useful for testing.

**Examples**

```r
## this example will not work correctly in example(try), but
## it does work correctly if pasted in
options(show.error.messages = FALSE)
try(log("a"))
print(.Last.value)
options(show.error.messages = TRUE)

## alternatively,
print(try(log("a"), TRUE))

## run a simulation, keep only the results that worked.
set.seed(123)
x <- stats::rnorm(50)
doit <- function(x)
{
  x <- sample(x, replace = TRUE)
  if(length(unique(x)) > 30) mean(x)
  else stop("too few unique points")
}

## alternative 1
res <- lapply(1:100, function(i) try(doit(x), TRUE))

## alternative 2
## Not run: res <- vector("list", 100)
```
for(i in 1:100) res[[i]] <- try(doit(x), TRUE)
## End(Not run)
unlist(res[sapply(res, function(x) !inherits(x, "try-error"))])

### typeof

**The Type of an Object**

**Description**

typeof determines the (R internal) type or storage mode of any object

**Usage**

typeof(x)

**Arguments**

- **x**: any R object.

**Value**

A character string. The possible values are listed in the structure `TypeTable` in `src/main/util.c`. Current values are the vector types "logical", "integer", "double", "complex", "character", "raw" and "list", "NULL", "closure" (function), "special" and "builtin" (basic functions and operators), "environment", "S4" (some S4 objects) and others that are unlikely to be seen at user level ("symbol", "pairlist", "promise", "language", "char", "...", "any", "expression", "externalptr", "bytecode" and "weakref").

**See Also**

- `mode`, `storage.mode`
- `isS4` to determine if an object has an S4 class.

**Examples**

typeof(2)
mode(2)

### unique

**Extract Unique Elements**

**Description**

unique returns a vector, data frame or array like x but with duplicate elements/rows removed.
Usage

unique(x, incomparables = FALSE, ...)  

## Default S3 method:  
unique(x, incomparables = FALSE, fromLast = FALSE,  
       nmax = NA, ...)  

## S3 method for class 'matrix'  
unique(x, incomparables = FALSE, MARGIN = 1,  
       fromLast = FALSE, ...)  

## S3 method for class 'array'  
unique(x, incomparables = FALSE, MARGIN = 1,  
       fromLast = FALSE, ...)  

Arguments

x a vector or a data frame or an array or NULL.  
incomparables a vector of values that cannot be compared. FALSE is a special value, meaning  
that all values can be compared, and may be the only value accepted for methods  
other than the default. It will be coerced internally to the same type as x.  

fromLast logical indicating if duplication should be considered from the last, i.e., the last  
(or rightmost) of identical elements will be kept. This only matters for names or  
dimnames.  

nmax the maximum number of unique items expected (greater than one). See duplicated.  

... arguments for particular methods.  

MARGIN the array margin to be held fixed: a single integer.  

Details

This is a generic function with methods for vectors, data frames and arrays (including matrices).  
The array method calculates for each element of the dimension specified by MARGIN if the remaining  
dimensions are identical to those for an earlier element (in row-major order). This would most  
commonly be used for matrices to find unique rows (the default) or columns (with MARGIN = 2).  

Note that unlike the Unix command uniq this omits duplicated and not just repeated elements/rows.  
That is, an element is omitted if it is equal to any previous element and not just if it is equal the  
immediately previous one. (For the latter, see rle).  

Missing values ("NA") are regarded as equal, numeric and complex ones differing from NaN; character strings will be compared in a “common encoding”; for details, see match (and duplicated)  
which use the same concept.  

Values in incomparables will never be marked as duplicated. This is intended to be used for a  
fairly small set of values and will not be efficient for a very large set.  

When used on a data frame with more than one column, or an array or matrix when comparing  
dimensions of length greater than one, this tests for identity of character representations. This will  
catch people who unwisely rely on exact equality of floating-point numbers!
Value

For a vector, an object of the same type of x, but with only one copy of each duplicated element. No attributes are copied (so the result has no names).

For a data frame, a data frame is returned with the same columns but possibly fewer rows (and with row names from the first occurrences of the unique rows).

A matrix or array is subsetted by [, drop = FALSE], so dimensions and dimnames are copied appropriately, and the result always has the same number of dimensions as x.

Warning

Using this for lists is potentially slow, especially if the elements are not atomic vectors (see vector) or differ only in their attributes. In the worst case it is \( O(n^2) \).

duplicated which gives the indices of duplicated elements.

rle which is the equivalent of the Unix uniq -c command.

Examples

```r
x <- c(3:5, 11:8, 8 + 0:5)
(ux <- unique(x))
(u2 <- unique(x, fromLast = TRUE)) # different order
stopifnot(identical(sort(ux), sort(u2)))

length(unique(sample(100, 100, replace = TRUE)))
## approximately 100(1 - 1/e) = 63.21

unique(iris)
```

unlink

Delete Files and Directories

Description

unlink deletes the file(s) or directories specified by x.

Usage

`unlink(x, recursive = FALSE, force = FALSE, expand = TRUE)`
Arguments

- **x**: a character vector with the names of the file(s) or directories to be deleted.
- **recursive**: logical. Should directories be deleted recursively?
- **force**: logical. Should permissions be changed (if possible) to allow the file or directory to be removed?
- **expand**: logical. Should wildcards (see 'Details' below) and tilde (see `path.expand`) be expanded?

Details

If `recursive = FALSE` directories are not deleted, not even empty ones.

On most platforms 'file' includes symbolic links, fifos and sockets. `unlink(x, recursive = TRUE)` deletes the just symbolic link if the target of such a link is a directory.

Wildcard expansion (normally '*' and '?' are allowed) is done by the internal code of `Sys.glob`. Wildcards never match a leading '.' in the filename, and files '.', '..', and '~' will never be considered for deletion. Wildcards will only be expanded if the system supports it. Most systems will support not only '*' and '?' but also character classes such as '[a-z]' (see the man pages for the system call `glob` on your OS). The metacharacters * ? [ can occur in Unix filenames, and this makes it difficult to use `unlink` to delete such files (see `file.remove`), although escaping the metacharacters by backslashes usually works. If a metacharacter matches nothing it is considered as a literal character.

`recursive = TRUE` might not be supported on all platforms, when it will be ignored, with a warning: however there are no known current examples.

Value

0 for success, 1 for failure, invisibly. Not deleting a non-existent file is not a failure, nor is being unable to delete a directory if `recursive = FALSE`. However, missing values in x are regarded as failures.

References

See Also

`file.remove`.

Description

Given a list structure x, `unlist` simplifies it to produce a vector which contains all the atomic components which occur in x.

Usage

`unlist(x, recursive = TRUE, use.names = TRUE)`
Arguments

- **x**: an R object, typically a list or vector.
- **recursive**: logical. Should unlisting be applied to list components of x?
- **use.names**: logical. Should names be preserved?

Details

unlist is generic: you can write methods to handle specific classes of objects, see `InternalMethods`, and note, e.g., `relist` with the `unlist` method for relistable objects.

If `recursive = FALSE`, the function will not recurse beyond the first level items in x.

Factors are treated specially. If all non-list elements of x are factor (or ordered factor) objects then the result will be a factor with levels the union of the level sets of the elements, in the order the levels occur in the level sets of the elements (which means that if all the elements have the same level set, that is the level set of the result).

x can be an atomic vector, but then `unlist` does nothing useful, not even drop names.

By default, `unlist` tries to retain the naming information present in x. If `use.names = FALSE` all naming information is dropped.

Where possible the list elements are coerced to a common mode during the unlisting, and so the result often ends up as a character vector. Vectors will be coerced to the highest type of the components in the hierarchy NULL < raw < logical < integer < double < complex < character < list < expression: pairlists are treated as lists.

A list is a (generic) vector, and the simplified vector might still be a list (and might be unchanged). Non-vector elements of the list (for example language elements such as names, formulas and calls) are not coerced, and so a list containing one or more of these remains a list. (The effect of unlisting an `lm` fit is a list which has individual residuals as components.) Note that `unlist(x)` now returns x unchanged also for non-vector x, instead of signalling an error in that case.

Value

NULL or an expression or a vector of an appropriate mode to hold the list components.

The output type is determined from the highest type of the components in the hierarchy NULL < raw < logical < integer < double < complex < character < list < expression, after coercion of pairlists to lists.

References

See Also

c, as.list, relist.

Examples

```r
unlist(options())
unlist(options(), use.names = FALSE)

l.ex <- list(a = list(1:5, LETTERS[1:5]), b = "Z", c = NA)
unlist(l.ex, recursive = FALSE)
unlist(l.ex, recursive = TRUE)
```
l1 <- list(a = "a", b = 2, c = pi+2i)
unlist(l1) # a character vector
l2 <- list(a = "a", b = as.name("b"), c = pi+2i)
unlist(l2) # remains a list
l1 <- list(as.name("sinc"), quote( a + b ), 1:10, letters, expression(1+x))
utils::str(l1)
for(x in l1)
  stopifnot(identical(x, unlist(x)))

---

**unname**

**Remove names or dimnames**

**Description**

Remove the `names` or `dimnames` attribute of an R object.

**Usage**

`unname(obj, force = FALSE)`

**Arguments**

`obj`  
an R object.

`force`  
logical; if true, the `dimnames` (names and row names) are removed even from `data.frames`.

**Value**

Object as `obj` but without `names` or `dimnames`.

**Examples**

```r
require(graphics); require(stats)

## Answering a question on R-help (14 Oct 1999):
col3 <- 750+ 100*r(t(1500, df = 3))
breaks <- factor(cut(col3, breaks = 360+5*(0:155)))
z <- table(breaks)
z[1:5] # The names are larger than the data ...
barplot(unname(z), axes = FALSE)
```
UseMethod  

Class Methods

Description

R possesses a simple generic function mechanism which can be used for an object-oriented style of programming. Method dispatch takes place based on the class(es) of the first argument to the generic function or of the object supplied as an argument to UseMethod or NextMethod.

Usage

UseMethod(generic, object)

NextMethod(generic = NULL, object = NULL, ...)

Arguments

generic      a character string naming a function (and not a built-in operator). Required for UseMethod.

object       for UseMethod: an object whose class will determine the method to be dispatched. Defaults to the first argument of the enclosing function.

...          further arguments to be passed to the next method.

Details

An R object is a data object which has a class attribute (and this can be tested by is.object). A class attribute is a character vector giving the names of the classes from which the object inherits. If the object does not have a class attribute, it has an implicit class. Matrices and arrays have class "matrix" or "array" followed by the class of the underlying vector. Most vectors have class the result of mode(x), except that integer vectors have class c("integer","numeric") and real vectors have class c("double","numeric"). When a function calling UseMethod("fun") is applied to an object with class attribute c("first","second"), the system searches for a function called fun.first and, if it finds it, applies it to the object. If no such function is found a function called fun.second is tried. If no class name produces a suitable function, the function fun.default is used, if it exists, or an error results.

Function methods can be used to find out about the methods for a particular generic function or class.

UseMethod is a primitive function but uses standard argument matching. It is not the only means of dispatch of methods, for there are internal generic and group generic functions. UseMethod currently dispatches on the implicit class even for arguments that are not objects, but the other means of dispatch do not.

NextMethod invokes the next method (determined by the class vector, either of the object supplied to the generic, or of the first argument to the function containing NextMethod if a method was invoked directly). Normally NextMethod is used with only one argument, generic, but if further arguments are supplied these modify the call to the next method.

NextMethod should not be called except in methods called by UseMethod or from internal generics (see InternalGenerics). In particular it will not work inside anonymous calling functions (e.g., get("print.ts")(AirPassengers)).
Namespaces can register methods for generic functions. To support this, `UseMethod` and `NextMethod` search for methods in two places: in the environment in which the generic function is called, and in the registration data base for the environment in which the generic is defined (typically a namespace). So methods for a generic function need to be available in the environment of the call to the generic, or they must be registered. (It does not matter whether they are visible in the environment in which the generic is defined.) As from R 3.5.0, the registration data base is searched after the top level environment (see `topenv`) of the calling environment (but before the parents of the top level environment).

**Technical Details**

Now for some obscure details that need to appear somewhere. These comments will be slightly different than those in Chambers(1992). (See also the draft ‘R Language Definition’.) `UseMethod` creates a new function call with arguments matched as they came in to the generic. Any local variables defined before the call to `UseMethod` are retained (unlike S). Any statements after the call to `UseMethod` will not be evaluated as `UseMethod` does not return. `UseMethod` can be called with more than two arguments: a warning will be given and additional arguments ignored. (They are not completely ignored in S.) If it is called with just one argument, the class of the first argument of the enclosing function is used as `object`: unlike S this is the first actual argument passed and not the current value of the object of that name.

`NextMethod` works by creating a special call frame for the next method. If no new arguments are supplied, the arguments will be the same in number, order and name as those to the current method but their values will be promises to evaluate their name in the current method and environment. Any named arguments matched to ... are handled specially: they either replace existing arguments of the same name or are appended to the argument list. They are passed on as the promise that was supplied as an argument to the current environment. (S does this differently!) If they have been evaluated in the current (or a previous environment) they remain evaluated. (This is a complex area, and subject to change: see the draft ‘R Language Definition’.)

The search for methods for `NextMethod` is slightly different from that for `UseMethod`. Finding no `fun.default` is not necessarily an error, as the search continues to the generic itself. This is to pick up an internal generic like `[]` which has no separate default method, and succeeds only if the generic is a primitive function or a wrapper for a `.Internal` function of the same name. (When a primitive is called as the default method, argument matching may not work as described above due to the different semantics of primitives.)

You will see objects such as `.Generic`, `.Method`, and `.Class` used in methods. These are set in the environment within which the method is evaluated by the dispatch mechanism, which is as follows:

1. Find the context for the calling function (the generic): this gives us the unevaluated arguments for the original call.
2. Evaluate the object (usually an argument) to be used for dispatch, and find a method (possibly the default method) or throw an error.
3. Create an environment for evaluating the method and insert special variables (see below) into that environment. Also copy any variables in the environment of the generic that are not formal (or actual) arguments.
4. Fix up the argument list to be the arguments of the call matched to the formals of the method.

`.Generic` is a length-one character vector naming the generic function.

`.Method` is a character vector (normally of length one) naming the method function. (For functions in the group generic `Ops` it is of length two.)

`.Class` is a character vector of classes used to find the next method. `NextMethod` adds an attribute "previous" to `.Class` giving the `.Class` last used for dispatch, and shifts `.Class` along to that used for dispatch.
.GenericCallEnv and .GenericDefEnv are the environments of the call to be generic and defining the generic respectively. (The latter is used to find methods registered for the generic.)

Note that .Class is set when the generic is called, and is unchanged if the class of the dispatching argument is changed in a method. It is possible to change the method that NextMethod would dispatch by manipulating .Class, but 'this is not recommended unless you understand the inheritance mechanism thoroughly' (Chambers & Hastie, 1992, p. 469).

Note

This scheme is called S3 (S version 3). For new projects, it is recommended to use the more flexible and robust S4 scheme provided in the methods package.

userhooks

Functions to Get and Set Hooks for Load, Attach, Detach and Unload

Description

These functions allow users to set actions to be taken before packages are attached/detached and namespaces are (un)loaded.

Usage

getHook(hookName)

setHook(hookName, value,
   action = c("append", "prepend", "replace"))

packageEvent(pkgname,
   event = c("onLoad", "attach", "detach", "onUnload"))

Arguments

hookName character string: the hook name
pkgname character string: the package/namespace name
event character string: an event for the package. Can be abbreviated.
value A function or a list of functions, or for action = "replace", NULL
action The action to be taken. Can be abbreviated.
Details

setHook provides a general mechanism for users to register hooks, a list of functions to be called from system (or user) functions. The initial set of hooks was associated with events on packages/namespaces: these hooks are named via calls to packageEvent.

To remove a hook completely, call setHook(hookName,NULL,"replace").

When an R package is attached by library or loaded by other means, it can call initialization code. See .onLoad for a description of the package hook functions called during initialization. Users can add their own initialization code via the hooks provided by setHook(), functions which will be called as funname(pkgname,pkgpath) inside a try call.

The sequence of events depends on which hooks are defined, and whether a package is attached or just loaded. In the case where all hooks are defined and a package is attached, the order of initialization events is as follows:

1. The package namespace is loaded.
2. The package’s .onLoad function is run.
3. If S4 methods dispatch is on, any actions set by setLoadAction are run.
4. The namespace is sealed.
5. The user’s “onLoad” hook is run.
6. The package is added to the search path.
7. The package’s .onAttach function is run.
8. The package environment is sealed.
9. The user’s “attach” hook is run.

A similar sequence (but in reverse) is run when a package is detached and its namespace unloaded:

1. The user’s “detach” hook is run.
2. The package’s .Last.lib function is run.
3. The package is removed from the search path.
4. The user’s “onUnload” hook is run.
5. The package’s .onUnload function is run.
6. The package namespace is unloaded.

Note that when an R session is finished, packages are not detached and namespaces are not unloaded, so the corresponding hooks will not be run.

Also note that some of the user hooks are run without the package being on the search path, so in those hooks objects in the package need to be referred to using the double (or triple) colon operator, as in the example.

If multiple hooks are added, they are normally run in the order shown by getHook, but the “detach” and “onUnload” hooks are run in reverse order so the default for package events is to add hooks ‘inside’ existing ones.

The hooks are stored in the environment .userHooksEnv in the base package, with ‘mangled’ names.

Value

For getHook function, a list of functions (possibly empty). For setHook function, no return value. For packageEvent, the derived hook name (a character string).
Note

Hooks need to be set before the event they modify: for standard packages this can be problematic as methods is loaded and attached early in the startup sequence. The usual place to set hooks such as the example below is in the `.Rprofile` file, but that will not work for methods.

See Also

library, detach, loadNamespace.

See :: for a discussion of the double and triple colon operators.

Other hooks may be added later: functions plot.new and persp already have them.

Examples

```r
setHook(packageEvent("grDevices", "onLoad"),
  function(...) grDevices::ps.options(horizontal = FALSE))
```

**utf8Conversion**  
*Convert Integer Vectors to or from UTF-8-encoded Character Vectors*

Description

Conversion of UTF-8 encoded character vectors to and from integer vectors representing a UTF-32 encoding.

Usage

```r
utf8ToInt(x)
intToUtf8(x, multiple = FALSE, allow_surrogate_pairs = FALSE)
```

Arguments

- `x` object to be converted.
- `multiple` logical: should the conversion be to a single character string or multiple individual characters?
- `allow_surrogate_pairs` logical: should interpretation of surrogate pairs be attempted? (See ‘Details’.) Only supported for `multiple = FALSE` and in R 3.5.0 and later.

Details

These will work in any locale, including on platforms that do not otherwise support multi-byte character sets.

Unicode defines a name and a number of all of the glyphs it encompasses: the numbers are called *code points*: since RFC3629 they run from 0 to 0x10FFFF (with about 12% being assigned by version 10.0 of the Unicode standard).

intToUtf8 does not by default handle surrogate pairs: inputs in the surrogate ranges are mapped to NA. They might occur if a UTF-16 byte stream has been read as 2-byte integers (in the correct byte order), in which case `allow_surrogate_pairs = TRUE` will try to interpret them (with unmatched surrogate values still treated as NA).
Value

utf8ToInt converts a length-one character string encoded in UTF-8 to an integer vector of Unicode code points.

intToUtf8 converts a numeric vector of Unicode code points either (default) to a single character string or a character vector of single characters. Non-integral numeric values are truncated to integers. For output to a single character string 0 is silently omitted: otherwise 0 is mapped to "". The Encoding of a non-NA return value is declared as "UTF-8".

Invalid and NA inputs are mapped to NA output.

Validity

Which code points are regarded as valid has changed over the lifetime of UTF-8. Originally all 32-bit unsigned integers were potentially valid and could be converted to up to 6 bytes in UTF-8. Since 2003 it has been stated that there will never be valid code points larger than 0x10FFFF, and so valid UTF-8 encodings are never more than 4 bytes.

The code points in the surrogate-pair range 0x0000 to 0x00FF are prohibited in UTF-8 and so are regarded as invalid by utf8ToInt and by default by intToUtf8.

The position of ‘noncharacters’ (notably 0xFFFE and 0xFFFF) was clarified by ‘Corrigendum 9’ in 2013. These are valid but will never be given an official interpretation. (In some earlier versions of R utf8ToInt treated them as invalid.)

References

Examples

```r
# will only display in some locales and fonts
intToUtf8(0x03B2L) # Greek beta
utf8ToInt("bi\u00dfchen")
utf8ToInt("\xfa\xb4\xbf\xbf\x9f")

## A valid UTF-16 surrogate pair (for U+10437)
x <- c(0x0801, 0xDC37)
intToUtf8(x)
intToUtf8(x, TRUE)
(xx <- intToUtf8(x, , TRUE)) # will only display in some locales and fonts
charToRaw(xx)

## Not run: ## An example of how surrogate pairs might occur
x <- "\U10437"
charToRaw(x)
foo <- tempfile()
writeLines(x, file(foo, encoding = "UTF-16LE"))

## next two are OS-specific, but are mandated by POSIX
system(paste("od -x", foo)) # 2-byte units, correct on little-endian platform
system(paste("od -t x1", foo)) # single bytes as hex
y <- readBin(foo, "integer", 2, 2, FALSE, endian = "little")
sprintf("%X", y)
intToUtf8(y, , TRUE)
```
UTF8filepaths

## End(Not run)

UTF8filepaths  

File Paths not in the Native Encoding

Description

Most modern file systems store file-path components (names of directories and files) in a character encoding of wide scope: usually UTF-8 on a Unix-alike and UCS-2/UTF-16 on Windows. However, this was not true when R was first developed and there are still exceptions amongst file systems, e.g. FAT32.

This was not something anticipated by the C and POSIX standards which only provide means to access files *via* file paths encoded in the current locale, for example those specified in Latin-1 in a Latin-1 locale.

Everything here apart from the specific section on Windows is about Unix-alikes.

Details

It is possible to mark character strings (elements of character vectors) as being in UTF-8 or Latin-1 (see Encoding). This allows file paths not in the native encoding to be expressed in R character vectors but there is almost no way to use them unless they can be translated to the native encoding. That is of course not a problem if that is UTF-8, so these details are really only relevant to the use of a non-UTF-8 locale (including a C locale) on a Unix-alike.

Functions to open a file such as `file`, `fifo`, `pipe`, `gzfile`, `bzfile`, `xzfile` and `unz` give an error for non-native filepaths. Where functions look at existence such as `file.exists`, `dir.exists`, `unlink`, `file.info` and `list.files`, non-native filepaths are treated as non-existent.

Many other functions use `file` or `gzfile` to open their files.

`file.path` allows non-native file paths to be combined, marking them as UTF-8 if needed.

`path.expand` only handles paths in the native encoding.

Windows

Windows provides proprietary entry points to access its file systems, and these gained ‘wide’ versions in Windows NT that allowed file paths in UCS-2/UTF-16 to be accessed from any locale.

Some R functions use these entry points when file paths are marked as Latin-1 or UTF-8 to allow access to paths not in the current encoding. These include

`file`, `file.access`, `file.append`, `file.copy`, `file.create`, `file.exists`, `file.info`,
`file.link`, `file.remove`, `file.rename`, `file.symlink`

and

`dir.create`, `dir.exists`, `normalizePath`, `path.expand`, `pipe`, `Sys.glob`, `Sys.junction`,
`unlink`

but not `gzfile` `bzfile`, `xzfile` nor `unz`.

For functions using `gzfile` (including `load`, `readRDS`, `read.dcf` and `tar`), it is often possible to use a `gzcon` connection wrapping a `file` connection.

Other notable exceptions are `list.files`, `list.dirs`, `system` and file-path inputs for graphics devices.
**validUTF8**

### Historical comment

Before R 4.0.0, file paths marked as being in Latin-1 or UTF-8 were silently translated to the native encoding using escapes such as `\xe7` or `\U00e7`. This created valid file names but maybe not those intended.

### Note

This document is still a work-in-progress.

---

### validUTF8

**Check if a Character Vector is Validly Encoded**

### Description

Check if each element of a character vector is valid in its implied encoding.

### Usage

```
validUTF8(x)
validEnc(x)
```

### Arguments

- `x` a character vector.

### Details

These use similar checks to those used by functions such as `grep`.

- `validUTF8` ignores any marked encoding (see `Encoding`) and so looks directly if the bytes in each string are valid UTF-8.
- `validEnc` regards character strings as validly encoded unless their encodings are marked as UTF-8 or they are unmarked and the R session is in a UTF-8 or other multi-byte locale. (The checks in other multi-byte locales depend on the OS and as with `iconv` not all invalid inputs may be detected.)

### Value

A logical vector of the same length as `x`. `NA` elements are regarded as validly encoded.

### Note

It would be possible to check for the validity of character strings in a Latin-1 encoding, but extensions such as CP1252 are widely accepted as ‘Latin-1’ and 8-bit encodings rarely need to be checked for validity.
Examples

```r
x <-
## from example(text)
c("Jetz", "no", "chli", "\z\xc3\xbcr\xc3\xbcb\xc3\xbchtsch:\", 
  "(noch", "ein", "\bi\xc3\xc9fchen", "\z\xc3\xbc", "deutsch")
## from a CRAN check log
  "\xfa\xb4\xbf\xbf\x9f")
validUTF8(x)
validEnc(x) # depends on the locale
Encoding(x) <- "UTF-8"
validEnc(x) # typically the last, x[10], is invalid

## Maybe advantageous to declare it "unknown":
G <- x ; Encoding(G[!validEnc(G)]) <- "unknown"
try( substr(x, 1,1) ) # gives 'invalid multibyte string' error
try( substr(G, 1,1) ) # works
nchar(G) # fine, too
## but it is not "more valid" typically:
all.equal(validEnc(x),
  validEnc(G)) # typically TRUE
```

---

vector | Vectors

Description

vector produces a vector of the given length and mode.

as.vector, a generic, attempts to coerce its argument into a vector of mode mode (the default is to coerce to whichever vector mode is most convenient): if the result is atomic all attributes are removed.

is.vector returns TRUE if x is a vector of the specified mode having no attributes other than names. It returns FALSE otherwise.

Usage

```r
vector(mode = "logical", length = 0)
as.vector(x, mode = "any")
is.vector(x, mode = "any")
```

Arguments

- **mode**: character string naming an atomic mode or "list" or "expression" or (except for vector) "any". Currently, is.vector() allows any type (see typeof) for mode, and when mode is not "any", is.vector(x,mode) is almost the same as typeof(x) == mode.

- **length**: a non-negative integer specifying the desired length. For a long vector, i.e., length > .Machine$integer.max, it has to be of type "double". Supplying an argument of length other than one is an error.

- **x**: an R object.
The atomic modes are "logical", "integer", "numeric" (synonym "double"), "complex", "character" and "raw".

If mode = "any", is.vector may return TRUE for the atomic modes, list and expression. For any mode, it will return FALSE if x has any attributes except names. (This is incompatible with S.)

On the other hand, as.vector removes all attributes including names for results of atomic mode (but not those of mode "list" nor "expression").

Note that factors are not vectors; is.vector returns FALSE and as.vector converts a factor to a character vector for mode = "any".

For vector, a vector of the given length and mode. Logical vector elements are initialized to FALSE, numeric vector elements to 0, character vector elements to "", raw vector elements to NULL bytes and list/expression elements to NULL.

For as.vector, a vector (atomic or of type list or expression). All attributes are removed from the result if it is of an atomic mode, but not in general for a list result. The default method handles 24 input types and 12 values of type: the details of most coercions are undocumented and subject to change.

For is.vector, TRUE or FALSE. is.vector(x, mode = "numeric") can be true for vectors of types "integer" or "double" whereas is.vector(x, mode = "double") can only be true for those of type "double".

Writers of methods for as.vector need to take care to follow the conventions of the default method. In particular

- Argument mode can be "any", any of the atomic modes, "list", "expression", "symbol", "pairlist" or one of the aliases "double" and "name".
- The return value should be of the appropriate mode. For mode = "any" this means an atomic vector or list.
- Attributes should be treated appropriately: in particular when the result is an atomic vector there should be no attributes, not even names.
- is.vector(as.vector(x, m), m) should be true for any mode m, including the default "any".

Note

as.vector and is.vector are quite distinct from the meaning of the formal class "vector" in the methods package, and hence as(x, "vector") and is(x, "vector").

Note that as.vector(x) is not necessarily a null operation if is.vector(x) is true: any names will be removed from an atomic vector.

Non-vector modes "symbol" (synonym "name") and "pairlist" are accepted but have long been undocumented: they are used to implement as.name and as.pairlist, and those functions should preferably be used directly. None of the description here applies to those modes: see the help for the preferred forms.

Vectorize

See Also
c, is.numeric, is.list, etc.

Examples

```r
df <- data.frame(x = 1:3, y = 5:7)
## Error:
try(as.vector(data.frame(x = 1:3, y = 5:7), mode = "numeric"))

x <- c(a = 1, b = 2)
is.vector(x)
as.vector(x)
all.equal(x, as.vector(x)) ## FALSE

###-- All the following are TRUE:
is.list(df)
! is.vector(df)
! is.vector(df, mode = "list")
is.vector(list(), mode = "list")
```

Description

Vectorize creates a function wrapper that vectorizes the action of its argument `FUN`.

Usage

```r
Vectorize(FUN, vectorize.args = arg.names, SIMPLIFY = TRUE,
USE.NAMES = TRUE)
```

Arguments

- **FUN**: function to apply, found via `match.fun`.
- **vectorize.args**: a character vector of arguments which should be vectorized. Defaults to all arguments of `FUN`.
- **SIMPLIFY**: logical or character string; attempt to reduce the result to a vector, matrix or higher dimensional array; see the `simplify` argument of `sapply`.
- **USE.NAMES**: logical; use names if the first ... argument has names, or if it is a character vector, use that character vector as the names.

Details

The arguments named in the `vectorize.args` argument to `Vectorize` are the arguments passed in the ... list to `mapply`. Only those that are actually passed will be vectorized; default values will not. See the examples.

`Vectorize` cannot be used with primitive functions as they do not have a value for `formals`. It also cannot be used with functions that have arguments named `FUN`, `vectorize.args`, `SIMPLIFY` or `USE.NAMES`, as they will interfere with the `Vectorize` arguments. See the `combn` example below for a workaround.
A function with the same arguments as FUN, wrapping a call to `mapply`.

**Examples**

```r
# We use rep.int as rep is primitive
df <- Vectorize(rep.int)  
df(1:4, 4:1)
df(t = 1:4, x = 4:1)

df <- Vectorize(rep.int, "times")  
df(t = 1:4, x = 4:2)

df <- function(x = 1:3, y) c(x, y)
df(1:3, 3:1)
df(t = 1:3, 3:1)
df(y = 1:3)  # Only vectorizes y, not x

# Nonlinear regression contour plot, based on nls() example
require(graphics)
SS <- function(Vm, K, resp, conc) {
  pred <- (Vm * conc)/(K + conc)
  sum((resp - pred)^2 / pred)
}
vSS <- Vectorize(SS, c("Vm", "K"))  
Treated <- subset(Puromycin, state == "treated")
Vv <- seq(140, 310, length.out = 50)
K <- seq(0, 0.15, length.out = 40)
SSvals <- outer(Vv, K, vSS, Treated$rate, Treated$conc)
contour(Vv, K, SSvals, levels = (1:10)^2, xlab = "Vm", ylab = "K")

# combn() has an argument named FUN
combnV <- Vectorize(function(x, m, FUNV = NULL) combn(x, m, FUN = FUNV),
                    vectorize.args = c("x", "m"))
combnV(4, 1:4)
combnV(4, 1:4, sum)
```

**Description**
Generates a warning message that corresponds to its argument(s) and (optionally) the expression or function from which it was called.

**Usage**

```r
warning(..., call. = TRUE, immediate. = FALSE, noBreaks. = FALSE, domain = NULL)
suppressWarnings(expr, classes = "warning")
```
 Arguments

... zero or more objects which can be coerced to character (and which are pasted together with no separator) or a single condition object.

call. logical, indicating if the call should become part of the warning message.

immediate. logical, indicating if the call should be output immediately, even if `getOption("warn") <= 0`.

noBreaks. logical, indicating as far as possible the message should be output as a single line when `getOption(warn = 1)`.

expr expression to evaluate.

domain see `gettext`. If NA, messages will not be translated, see also the note in `stop`.

classes character, indicating which classes of warnings should be suppressed.

 Details

The result depends on the value of `options("warn")` and on handlers established in the executing code.

If a condition object is supplied it should be the only argument, and further arguments will be ignored, with a message.

`warning` signals a warning condition by (effectively) calling `signalCondition`. If there are no handlers or if all handlers return, then the value of `warn = getOption("warn")` is used to determine the appropriate action. If `warn` is negative warnings are ignored; if it is zero they are stored and printed after the top–level function has completed; if it is one they are printed as they occur and if it is 2 (or larger) warnings are turned into errors. Calling `warning(immediate = TRUE)` turns `warn <= 0` into `warn = 1` for this call only.

If `warn` is zero (the default), a read-only variable `last.warning` is created. It contains the warnings which can be printed via a call to `warnings`.

Warnings will be truncated to `getOption("warning.length")` characters, default 1000, indicated by `[... truncated]`.

While the warning is being processed, a `muffleWarning` restart is available. If this restart is invoked with `invokeRestart`, then warning returns immediately.

An attempt is made to coerce other types of inputs to `warning` to character vectors.

`suppressWarnings` evaluates its expression in a context that ignores all warnings.

 Value

The warning message as `character` string, invisibly.

 References

 See Also

`stop` for fatal errors, `message` for diagnostic messages, `warnings`, and `options` with argument `warn=`.

`gettext` for the mechanisms for the automated translation of messages.
**Examples**

```r
# Example 1
testit <- function() warning("testit")
testit() ## shows call

# Example 2
testit <- function() warning("problem in testit", call. = FALSE)
testit() ## no call

# Example 3
suppressWarnings(warning("testit"))
```

**Description**

`warnings` and its print method print the variable `last.warning` in a pleasing form.

**Usage**

```r
warnings(...)  
## S3 method for class 'warnings'
summary(object, ...)

## S3 method for class 'warnings'
print(x, ...)

## S3 method for class 'summary.warnings'
print(x, ...)
```

**Arguments**

- `...` arguments to be passed to `cat` (for `warnings()`).
- `object` a "warnings" object as returned by `warnings()`.
- `x` a "warnings" or "summary.warnings" object.
- `tags` if not missing, a `character` vector of the same `length` as `x`, to "label" the messages. Defaults to `paste0(seq_len(n), ": ")` for `n ≥ 2` where `n < -length(x)`. 
- `header` a character string `cat()`ed before the messages are printed.

**Details**

See the description of `options("warn")` for the circumstances under which there is a `last.warning` object and `warnings()` is used. In essence this is if `options(warn = 0)` and warning has been called at least once.

Note that the `length(last.warning)` is maximally `getOption("nwarnings")` (at the time the warnings are generated) which is 50 by default. To increase, use something like

```r
options(nwarnings = 10000)
```

It is possible that `last.warning` refers to the last recorded warning and not to the last warning, for example if `options(warn) has been changed or if a catastrophic error occurred.
Value

`warnings()` returns an object of S3 class "warnings", basically a named `list`. `summary(<warnings>)` returns a "summary.warnings" object which is basically the `list` of unique warnings (`unique(object)`) with a "counts" attribute, somewhat experimentally.

Warning

It is undocumented where `last.warning` is stored nor that it is visible, and this is subject to change.

References

See Also

`warning`.

Examples

```r
## NB this example is intended to be pasted in,
## rather than run by example()
ow <- options("warn")
for(w in -1:1) {
  options(warn = w); cat("\n warn =", w, "\n")
  for(i in 1:3) { cat(i,"..\n"); m <- matrix(1:7, 3,4) }
  cat("--==--==--\n")
}
## at the end prints all three warnings, from the 'option(warn = 0)' above
options(ow) # reset to previous, typically 'warn = 0'

## Often the most useful way to look at many warnings:
summary(warnings())
```

```r
op <- options(nwarnings = 10000) ## <- get "full statistics"
x <- 1:36; for(n in 1:13) for(m in 1:12) A <- matrix(x, n,m) # There were 105 warnings ...
summary(warnings())
options(op) # revert to previous (keeping 50 messages by default)
```

Description

Extract the weekday, month or quarter, or the Julian time (days since some origin). These are generic functions: the methods for the internal date-time classes are documented here.
Usage

```r
weekdays(x, abbreviate)
## S3 method for class 'POSIXt'
weekdays(x, abbreviate = FALSE)
## S3 method for class 'Date'
weekdays(x, abbreviate = FALSE)

months(x, abbreviate)
## S3 method for class 'POSIXt'
months(x, abbreviate = FALSE)
## S3 method for class 'Date'
months(x, abbreviate = FALSE)

quarters(x, abbreviate)
## S3 method for class 'POSIXt'
quarters(x, ...)
## S3 method for class 'Date'
quarters(x, ...)

julian(x, ...)
## S3 method for class 'POSIXt'
julian(x, origin = as.POSIXct("1970-01-01", tz = "GMT"), ...)  
## S3 method for class 'Date'
julian(x, origin = as.Date("1970-01-01"), ...)
```

Arguments

- `x` an object inheriting from class "POSIXt" or "Date".
- `abbreviate` logical vector (possibly recycled). Should the names be abbreviated?
- `origin` an length-one object inheriting from class "POSIXt" or "Date".
- `...` arguments for other methods.

Value

- `weekdays` and `months` return a character vector of names in the locale in use.
- `quarters` returns a character vector of "Q1" to "Q4".
- `julian` returns the number of days (possibly fractional) since the origin, with the origin as a "origin" attribute. All time calculations in R are done ignoring leap-seconds.

Note

Other components such as the day of the month or the year are very easy to compute: just use `as.POSIXlt` and extract the relevant component. Alternatively (especially if the components are desired as character strings), use `strftime`.

- `DateTimeClasses`, `Date`
which

Examples

weekdays(.leap.seconds)
months(.leap.seconds)
quarters(.leap.seconds)

## Show how easily you get month, day, year, day (of {month, week, yr}), ... :
## (remember to count from 0 (!): mon = 0..11, wday = 0..6, etc !)

##' Transform (Time-)Date vector to convenient data frame :
dt2df <- function(dt, dName = deparse(substitute(dt)), stringsAsFactors = FALSE) {
  DF <- as.data.frame(unclass(as.POSIXlt(dt)), stringsAsFactors=stringsAsFactors)
  'names<-'(cbind(dt, DF, deparse.level=0L), c(dName, names(DF)))
}
## e.g.,
dt2df(.leap.seconds) # date+time
dt2df(Sys.Date() + 0:9) # date

## Even simpler: Date -> Matrix - dropping time info {sec,min,hour, isdst}
d2mat <- function(x) simplify2array(unclass(as.POSIXlt(x))[4:7])
## e.g.,
d2mat(seq(as.Date("2000-02-02"), by=1, length.out=30)) # has R 1.0.0's release date

## is the number of days since noon UTC on the first day of 4317 BC.
## in the proleptic Julian calendar. To more recently, in
## 'Terrestrial Time' which differs from UTC by a few seconds
## See https://en.wikipedia.org/wiki/Terrestrial_Time
julian(Sys.Date(), -2440588) # from a day
floor(as.numeric(julian(Sys.time())) + 2440587.5) # from a date-time

which

Which indices are TRUE?

Description

Give the TRUE indices of a logical object, allowing for array indices.

Usage

which(x, arr.ind = FALSE, useNames = TRUE)
arrayInd(ind, .dim, .dimnames = NULL, useNames = FALSE)

Arguments

x a logical vector or array. NAs are allowed and omitted (treated as if FALSE).
arr.ind logical; should array indices be returned when x is an array?
ind integer-valued index vector, as resulting from which(x).
.dim dim(.) integer vector
.dimnames optional list of character dimnames(.). If useNames is true, to be used for constructing dimnames for arrayInd() (and hence, which(*,arr.ind=TRUE)). If names(.dimnames) is not empty, these are used as column names. .dimnames[[1]] is used as row names.
which

useNames logical indicating if the value of arrayInd() should have (non-null) dimnames at all.

Value

If arr.ind == FALSE (the default), an integer vector, or a double vector if x is a long vector, with length equal to \( \text{sum}(x) \), i.e., to the number of TRUEs in x.

Basically, the result is \((1: \text{length}(x))[x]\) in typical cases; more generally, including when x has \(\text{NA}\)'s, \(\text{which}(x)\) is \(\text{seq_along}(x)[!\text{is.na}(x) \& x]\) plus names when x has.

If arr.ind == TRUE and x is an array (has a dim attribute), the result is arrayInd(which(x),dim(x),dimnames(x)), namely a matrix whose rows each are the indices of one element of x; see Examples below.

Note

Unlike most other base R functions this does not coerce x to logical: only arguments with typeof logical are accepted and others give an error.

Author(s)

Werner Stahel and Peter Holzer (ETH Zurich) proposed the arr.ind option.

See Also

Logic, which.min for the index of the minimum or maximum, and match for the first index of an element in a vector, i.e., for a scalar a, match(a,x) is equivalent to \( \text{min}(\text{which}(x == a)) \) but much more efficient.

Examples

\[
\text{which(LETTERS == "R")}
\]

\[
\text{which(ll <- c(TRUE, FALSE, TRUE, NA, FALSE, FALSE, TRUE)) \#> 1 3 7}
\]

\[
\text{names(ll) <- letters[seq(ll)]}
\]

\[
\text{which(ll)}
\]

\[
\text{which((1:12)%%2 == 0) \# which are even?}
\]

\[
\text{which(1:10 > 3, arr.ind = TRUE)}
\]

\[
\text{( m <- matrix(1:12, 3, 4) )}
\]

\[
\text{div.3 <- m \mod{3} == 0}
\]

\[
\text{which(div.3)}
\]

\[
\text{which(div.3, arr.ind = TRUE)}
\]

\[
\text{rownames(m) <- paste(\"Case\", 1:3, sep = \"\_")}
\]

\[
\text{which(m \mod{5} == 0, arr.ind = TRUE)}
\]

\[
\text{dim(m) <- c(2, 2, 3); m}
\]

\[
\text{which(div.3, arr.ind = FALSE)}
\]

\[
\text{which(div.3, arr.ind = TRUE)}
\]

\[
\text{vm <- c(m)}
\]

\[
\text{dim(vm) <- length(vm) \#-- funny thing with length(dim(...)) == 1}
\]

\[
\text{which(div.3, arr.ind = TRUE)}
\]
which.min

Where is the Min() or Max() or first TRUE or FALSE?

Description

Determines the location, i.e., index of the (first) minimum or maximum of a numeric (or logical) vector.

Usage

which.min(x)
which.max(x)

Arguments

x numeric (logical, integer or double) vector or an R object for which the internal coercion to double works whose min or max is searched for.

Value

Missing and NaN values are discarded.
an integer or on 64-bit platforms, if length(x) =: n ≥ 2^{31} an integer valued double of length 1 or 0 (iff x has no non-NAs), giving the index of the first minimum or maximum respectively of x.
If this extremum is unique (or empty), the results are the same as (but more efficient than) which(x == min(x,na.rm = TRUE)) or which(x == max(x,na.rm = TRUE)) respectively.

Logical x – First TRUE or FALSE

For a logical vector x with both FALSE and TRUE values, which.min(x) and which.max(x) return the index of the first FALSE or TRUE, respectively, as FALSE < TRUE. However, match(FALSE, x) or match(TRUE, x) are typically preferred, as they do indicate mismatches.

Author(s)

Martin Maechler

See Also

which, max.col, max, etc.
Use arrayInd(), if you need array/matrix indices instead of 1D vector ones.
which.is.max in package nnet differs in breaking ties at random (and having a ‘fuzz’ in the definition of ties).

Examples

x <- c(1:4, 0:5, 11)
which.min(x)
which.max(x)

## it *does* work with NA’s present, by discarding them:
presidents[1:30]
with(presidents, na.rm = TRUE)
which.min(presidents) # 28
which.max(presidents) # 2

## Find the first occurrence, i.e. the first TRUE, if there is at least one:
x <- rpois(10000, lambda = 10); x[sample.int(50, 20)] <- NA
## where is the first value >= 20 ?
which.max(x >= 20)

## Also works for lists (which can be coerced to numeric vectors):
which.min(list(A = 7, pi = pi)) #> c(pi = 3.14159265358979L)

---

with  Evaluate an Expression in a Data Environment

Description

Evaluate an R expression in an environment constructed from data, possibly modifying (a copy of) the original data.

Usage

\[
\text{with(data, expr, ...)}
\]

within(data, expr, ...)

## S3 method for class 'list'
within(data, expr, keepAttrs = TRUE, ...)

Arguments

data data to use for constructing an environment. For the default with method this may be an environment, a list, a data frame, or an integer as in `sys.call`. For within, it can be a list or a data frame.

expr expression to evaluate; particularly for `within()` often a “compound” expression, i.e., of the form

\[
\begin{align*}
\{ \\
\text{a <- somefun()} \\
\text{b <- otherfun()} \\
\ldots \\
\text{rm(unused1, temp)} \\
\}
\end{align*}
\]

keepAttrs for the list method of within(), a logical specifying if the resulting list should keep the attributes from data and have its names in the same order. Often this is unneeded as the result is a named list anyway, and then keepAttrs = FALSE is more efficient.

... arguments to be passed to (future) methods.
with is a generic function that evaluates expr in a local environment constructed from data. The environment has the caller’s environment as its parent. This is useful for simplifying calls to modeling functions. (Note: if data is already an environment then this is used with its existing parent.) Note that assignments within expr take place in the constructed environment and not in the user’s workspace.

within is similar, except that it examines the environment after the evaluation of expr and makes the corresponding modifications to a copy of data (this may fail in the data frame case if objects are created which cannot be stored in a data frame), and returns it. within can be used as an alternative to transform.

Value

For with, the value of the evaluated expr. For within, the modified object.

Note

For interactive use this is very effective and nice to read. For programming however, i.e., in one’s functions, more care is needed, and typically one should refrain from using with(), as, e.g., variables in data may accidentally override local variables, see the reference.

Further, when using modeling or graphics functions with an explicit data argument (and typically using formulas), it is typically preferred to use the data argument of that function rather than to use with(data,…).

References

See Also
evalq, attach, assign, transform.

Examples

with(mtcars, mpg[cyl == 8 & disp > 350])  # is the same as, but nicer than mtcars$mpg[mtcars$cyl == 8 & mtcars$disp > 350]

require(stats); require(graphics)

# examples from glm:
with(data.frame(u = c(5,10,15,20,30,40,60,80,100),
    lot1 = c(118,58,42,35,27,25,21,19,18),
    lot2 = c(69,35,26,21,18,16,13,12,12)),
    list(summary(glm(lot1 ~ log(u), family = Gamma)),
     summary(glm(lot2 ~ log(u), family = Gamma))))

aq <- within(airquality, { # Notice that multiple vars can be changed
    Ozone <- log(Ozone)
    Month <- factor(month.abb[Month])
    cTemp <- round((Temp - 32) * 5/9, 1) # From Fahrenheit to Celsius
    S.CT <- Solar.R / cTemp # using the newly created variable
    rm(Day, Temp) })
# example from boxplot:
with(ToothGrowth, {
    boxplot(len ~ dose, boxwex = 0.25, at = 1:3 - 0.2,
        subset = (supp == "VC"), col = "yellow",
        main = "Guinea Pigs' Tooth Growth",
        xlab = "Vitamin C dose mg",
        ylab = "tooth length", ylim = c(0, 35))
    boxplot(len ~ dose, add = TRUE, boxwex = 0.25, at = 1:3 + 0.2,
        subset = supp == "OJ", col = "orange")
    legend(2, 9, c("Ascorbic acid", "Orange juice"),
        fill = c("yellow", "orange"))
})

# alternate form that avoids subset argument:
with(subset(ToothGrowth, supp == "VC"),
    boxplot(len ~ dose, boxwex = 0.25, at = 1:3 - 0.2,
        col = "yellow", main = "Guinea Pigs' Tooth Growth",
        xlab = "Vitamin C dose mg",
        ylab = "tooth length", ylim = c(0, 35)))
with(subset(ToothGrowth, supp == "OJ"),
    boxplot(len ~ dose, add = TRUE, boxwex = 0.25, at = 1:3 + 0.2,
        col = "orange")
legend(2, 9, c("Ascorbic acid", "Orange juice"),
    fill = c("yellow", "orange"))

---

**withVisible**  

*Return both a Value and its Visibility*

**Description**

This function evaluates an expression, returning it in a two element list containing its value and a flag showing whether it would automatically print.

**Usage**

```r
withVisible(x)
```

**Arguments**

- `x`  
an expression to be evaluated.

**Details**

The argument, *not* an `expression` object, rather an (unevaluated function) `call`, is evaluated in the caller's context.

This is a *primitive* function.
Value

value The value of x after evaluation.
visible logical; whether the value would auto-print.

See Also

invisible, eval; withAutoprint() calls source() which itself uses withVisible() in order to correctly “auto print”.

Examples

x <- 1
withVisible(x <- 1) # $visible is FALSE
x
withVisible(x) # $visible is TRUE

# Wrap the call in evalq() for special handling
df <- data.frame(a = 1:5, b = 1:5)
evalq(withVisible(a + b), envir = df)

---

write Write Data to a File

Description

The data (usually a matrix) x are written to file file. If x is a two-dimensional matrix you need to transpose it to get the columns in file the same as those in the internal representation.

Usage

write(x, file = "data",
ncolumns = if(is.character(x)) 1 else 5,
append = FALSE, sep = " ")

Arguments

x the data to be written out, usually an atomic vector.
file a connection, or a character string naming the file to write to. If "", print to the standard output connection. When .Platform$OS.type != "windows", and it is "|cmd", the output is piped to the command given by ‘cmd’.
ncolumns the number of columns to write the data in.
append if TRUE the data x are appended to the connection.
sep a string used to separate columns. Using sep = "\t" gives tab delimited output; default is " ".

References

See Also

write is a wrapper for cat, which gives further details on the format used.
save for writing any R objects, write.table for data frames, and scan for reading data.

Examples

# create a 2 by 5 matrix
x <- matrix(1:10, ncol = 5)

fil <- tempfile("data")
# the file data contains x, two rows, five cols
# 1 3 5 7 9 will form the first row
write(t(x), fil)
if(interactive()) file.show(fil)
unlink(fil) # tidy up

# Writing to the "console" 'tab-delimited'
# two rows, five cols but the first row 1 2 3 4 5
write(x, "", sep = "\t")

writeLines  Write Lines to a Connection

Description

Write text lines to a connection.

Usage

writeLines(text, con = stdout(), sep = "\n", useBytes = FALSE)

Arguments

text  A character vector
con   A connection object or a character string.
sep character string. A string to be written to the connection after each line of text.
useBytes logical. See ‘Details’.

Details

If the con is a character string, the function calls file to obtain a file connection which is opened
for the duration of the function call.
If the connection is open it is written from its current position. If it is not open, it is opened for the
duration of the call in "wt" mode and then closed again.
Normally writeLines is used with a text-mode connection, and the default separator is converted to
the normal separator for that platform (LF on Unix/Linux, CRLF on Windows). For more control,
open a binary connection and specify the precise value you want written to the file in sep. For even
more control, use writeChar on a binary connection.
useBytes is for expert use. Normally (when false) character strings with marked encodings are
converted to the current encoding before being passed to the connection (which might do further
re-encoding. useBytes = TRUE suppresses the re-encoding of marked strings so they are passed byte-by-byte to the connection: this can be useful when strings have already been re-encoded by e.g. iconv. (It is invoked automatically for strings with marked encoding "bytes".)

See Also

connections, writeChar, writeBin, readLines, cat

xtfrm Auxiliary Function for Sorting and Ranking

Description

A generic auxiliary function that produces a numeric vector which will sort in the same order as x.

Usage

xtfrm(x)

Arguments

x an R object.

Details

This is a special case of ranking, but as a less general function than rank is more suitable to be made generic. The default method is similar to rank(x, ties.method = "min", na.last = "keep"), so NA values are given rank NA and all tied values are given equal integer rank.

The factor method extracts the codes.

The default method will unclass the object if is.numeric(x) is true but otherwise make use of == and > methods for the class of x[i] (for integers i), and the is.na method for the class of x, but might be rather slow when doing so.

This is an internal generic primitive, so S3 or S4 methods can be written for it.

Value

A numeric (usually integer) vector of the same length as x.

See Also

rank, sort, order.
zapsmall

Description

zapsmall determines a digits argument dr for calling \texttt{round(x, digits = dr)} such that values close to zero (compared with the maximal absolute value) are ‘zapped’, i.e., replaced by 0.

Usage

\begin{verbatim}
zapsmall(x, digits = getOption("digits"))
\end{verbatim}

Arguments

- \texttt{x}: a numeric or complex vector or any \texttt{R} number-like object which has a \texttt{round} method and basic arithmetic methods including \texttt{log10}.
- \texttt{digits}: integer indicating the precision to be used.

References

Examples

\begin{verbatim}
x2 <- pi * 100^(-1:3)
print(x2 / 1000, digits = 4)
zapsmall(x2 / 1000, digits = 4)
zapsmall(exp(1i*0:4*pi/2))
\end{verbatim}

zpackages

Listing of Packages

Description

\texttt{.packages} returns information about package availability.

Usage

\begin{verbatim}
.packages(all.available = FALSE, lib.loc = NULL)
\end{verbatim}

Arguments

- \texttt{all.available}: logical; if \texttt{TRUE} return a character vector of all available packages in \texttt{lib.loc}.
- \texttt{lib.loc}: a character vector describing the location of \texttt{R} library trees to search through, or \texttt{NULL}. The default value of \texttt{NULL} corresponds to \texttt{.libPaths}.
Details

.packages() returns the names of the currently attached packages invisibly whereas .packages(all.available = TRUE) gives (visibly) all packages available in the library location path lib.loc.

For a package to be regarded as being ‘available’ it must have valid metadata (and hence be an installed package). However, this will report a package as available if the metadata does not match the directory name: use find.package to confirm that the metadata match or installed.packages for a much slower but more comprehensive check of ‘available’ packages.

Value

A character vector of package base names, invisible unless all.available = TRUE.

Note

.packages(all.available = TRUE) is not a way to find out if a small number of packages are available for use: not only is it expensive when thousands of packages are installed, it is an incomplete test. See the help for find.package for why require should be used.

Author(s)

R core; Guido Masarotto for the all.available = TRUE part of .packages.

See Also

library, .libPaths, installed.packages.

Examples

(.packages()) # maybe just "base"
.packages(all.available = TRUE) # return all available as character vector
require(splines)
(.packages()) # "splines", too
detach("package:splines")

Description

Miscellaneous internal/programming utilities.

Usage

.standard_regexps()

Details

.standard_regexps returns a list of ‘standard’ regexps, including elements named valid_package_name and valid_package_version with the obvious meanings. The regexps are not anchored.
Chapter 2

The compiler package

---

**compile**  
**Byte Code Compiler**

---

**Description**

These functions provide an interface to a byte code compiler for R.

**Usage**

```r
cmpfun(f, options = NULL)
compile(e, env = .GlobalEnv, options = NULL, srcref = NULL)
cmpfile(infile, outfile, ascii = FALSE, env = .GlobalEnv,
    verbose = FALSE, options = NULL, version = NULL)
loadcmp(file, envir = .GlobalEnv, chdir = FALSE)
disassemble(code)
enableJIT(level)
compilePKGS(enable)
getCompilerOption(name, options)
setCompilerOptions(...)
```

**Arguments**

- **f**: a closure.
- **options**: list of named compiler options: see ‘Details’.
- **env**: the top level environment for the compiling.
- **srcref**: initial source reference for the expression.
- **file, infile, outfile**: pathnames; outfile defaults to infile with a ‘.Rc’ extension in place of any existing extension.
- **ascii**: logical; should the compiled file be saved in ascii format?
- **verbose**: logical; should the compiler show what is being compiled?
- **version**: the workspace format version to use. NULL specifies the current default format (3). Version 1 was the default from R 0.99.0 to R 1.3.1 and version 2 from R 1.4.0 to 3.5.0. Version 3 is supported from R 3.5.0.
compile

envir environment to evaluate loaded expressions in.
chdir logical; change directory before evaluation?
code byte code expression or compiled closure
e expression to compile.
level integer; the JIT level to use (0 to 3, or negative to return it).
enable logical; enable compiling packages if TRUE.
name character string; name of option to return.
... named compiler options to set.

Details

The function cmpfun compiles the body of a closure and returns a new closure with the same formals and the body replaced by the compiled body expression.

compile compiles an expression into a byte code object; the object can then be evaluated with eval.
cmpfile parses the expressions in infile, compiles them, and writes the compiled expressions to outfile. If outfile is not provided, it is formed from infile by replacing or appending a .Rc suffix.
loadcmp is used to load compiled files. It is similar to sys.source, except that its default loading environment is the global environment rather than the base environment.
disassemble produces a printed representation of the code that may be useful to give a hint of what is going on.
enableJIT enables or disables just-in-time (JIT) compilation. JIT is disabled if the argument is 0. If level is 1 then larger closures are compiled before their first use. If level is 2, then some small closures are also compiled before their second use. If level is 3 then in addition all top level loops are compiled before they are executed. JIT level 3 requires the compiler option optimize to be 2 or 3. The JIT level can also be selected by starting R with the environment variable R_ENABLE_JIT set to one of these values. Calling enableJIT with a negative argument returns the current JIT level. The default JIT level is 3.
compilePKGS enables or disables compiling packages when they are installed. This requires that the package uses lazy loading as compilation occurs as functions are written to the lazy loading data base. This can also be enabled by starting R with the environment variable _R_COMPILE_PKGS_ set to a positive integer value. This should not be enabled outside package installation, because it causes any serialized function to be compiled, which comes with time and space overhead. R_COMPILE_PKGS can be used, instead, to instruct INSTALL to enable/disable compilation of packages during installation.
Currently the compiler warns about a variety of things. It does this by using cat to print messages. Eventually this should use the condition handling mechanism.
The options argument can be used to control compiler operation. There are currently four options: optimize, suppressAll, suppressUndefined, and suppressNoSuperAssignVar. optimize specifies the optimization level, an integer from 0 to 3 (the current out-of-the-box default is 2). suppressAll should be a scalar logical; if TRUE no messages will be shown (this is the default). suppressUndefined can be TRUE to suppress all messages about undefined variables, or it can be a character vector of the names of variables for which messages should not be shown. suppressNoSuperAssignVar can be TRUE to suppress messages about super assignments to a variable for which no binding is visible at compile time. During compilation of packages, suppressAll is currently FALSE, suppressUndefined is TRUE and suppressNoSuperAssignVar is TRUE.
getCompilerOption returns the value of the specified option. The default value is returned unless a value is supplied in the options argument; the options argument is primarily for internal use.
setCompilerOption sets the default option values. Options to set are identified by argument names, e.g. setCompilerOptions(suppressAll = TRUE, optimize = 3). It returns a named list of the previous values.

Calling the compiler a byte code compiler is actually a bit of a misnomer: the external representation of code objects currently uses int operands, and when compiled with gcc the internal representation is actually threaded code rather than byte code.

enableJIT(oldJIT)
Chapter 3

The datasets package

**Description**
Base R datasets

**Details**
This package contains a variety of datasets. For a complete list, use `library(help = "datasets")`.

**Author(s)**
R Core Team and contributors worldwide
Maintainer: R Core Team <R-core@r-project.org>

**ability.cov**

**Description**
Six tests were given to 112 individuals. The covariance matrix is given in this object.

**Usage**

ability.cov
Details

The tests are described as

- **general**: a non-verbal measure of general intelligence using Cattell’s culture-fair test.
- **picture**: a picture-completion test
- **blocks**: block design
- **maze**: mazes
- **reading**: reading comprehension
- **vocab**: vocabulary

Bartholomew gives both covariance and correlation matrices, but these are inconsistent. Neither are in the original paper.

Examples

```r
require(stats)
(ability.FA <- factanal(factors = 1, covmat = ability.cov))
update(ability.FA, factors = 2)
## The signs of factors and hence the signs of correlations are
## arbitrary with promax rotation.
update(ability.FA, factors = 2, rotation = "promax")
```

### airmiles

**Passenger Miles on Commercial US Airlines, 1937–1960**

Description

The revenue passenger miles flown by commercial airlines in the United States for each year from 1937 to 1960.

Usage

`airmiles`

Format

AirPassengers

Source
F.A.A. Statistical Handbook of Aviation.

References

Examples

```r
require(graphics)
plot(airmiles, main = "airmiles data",
     xlab = "Passenger-miles flown by U.S. commercial airlines", col = 4)
```

---

**AirPassengers**

*Monthly Airline Passenger Numbers 1949-1960*

Description
The classic Box & Jenkins airline data. Monthly totals of international airline passengers, 1949 to 1960.

Usage
AirPassengers

Format
A monthly time series, in thousands.

Source

Examples

```r
## Not run:
## These are quite slow and so not run by example(AirPassengers)
## The classic 'airline model', by full ML
(fit <- arima(log10(AirPassengers), c(0, 1, 1),
        seasonal = list(order = c(0, 1, 1), period = 12)))
update(fit, method = "CSS")
update(fit, x = window(log10(AirPassengers), start = 1954))
pred <- predict(fit, n.ahead = 24)
tl <- pred$Pred - 1.96 * pred$se
tu <- pred$Pred + 1.96 * pred$se
ts.ts.plot(AirPassengers, 10^tl, 10^tu, log = "y", lty = c(1, 2, 2))

## full ML fit is the same if the series is reversed, CSS fit is not
ap0 <- rev(log10(AirPassengers))
attributes(ap0) <- attributes(AirPassengers)
arima(ap0, c(0, 1, 1), seasonal = list(order = c(0, 1, 1), period = 12))
```
arima(ap0, c(0, 1, 1), seasonal = list(order = c(0, 1, 1), period = 12),
    method = "CSS")

## Structural Time Series
ap <- log10(AirPassengers) - 2
(fit <- StructTS(ap, type = "BSM"))
par(mfrow = c(1, 2))
plot(cbind(ap, fitted(fit)), plot.type = "single")
plot(cbind(ap, tsSmooth(fit)), plot.type = "single")

## End(Not run)

### airquality

#### New York Air Quality Measurements

**Description**

**Usage**

`airquality`

**Format**

A data frame with 153 observations on 6 variables.

[,1] Ozone numeric Ozone (ppb)
[,3] Wind numeric Wind (mph)
[,4] Temp numeric Temperature (degrees F)
[,5] Month numeric Month (1–12)

**Details**

Daily readings of the following air quality values for May 1, 1973 (a Tuesday) to September 30, 1973.

- **Ozone**: Mean ozone in parts per billion from 1300 to 1500 hours at Roosevelt Island
- **Solar.R**: Solar radiation in Langley's in the frequency band 4000–7700 Angstroms from 0800 to 1200 hours at Central Park
- **Wind**: Average wind speed in miles per hour at 0700 and 1000 hours at LaGuardia Airport
- **Temp**: Maximum daily temperature in degrees Fahrenheit at La Guardia Airport

**Source**

The data were obtained from the New York State Department of Conservation (ozone data) and the National Weather Service (meteorological data).
References

Examples

```r
require(graphics)
pairs(airquality, panel = panel.smooth, main = "airquality data")
```

---

**anscombe**  

*Anscombe’s Quartet of ‘Identical’ Simple Linear Regressions*

Description

Four \( x \times y \) datasets which have the same traditional statistical properties (mean, variance, correlation, regression line, etc.), yet are quite different.

Usage

`anscombe`

Format

A data frame with 11 observations on 8 variables.

- \( x_1 = x_2 = x_3 \) the integers 4:14, specially arranged
- \( x_4 \) values 8 and 19
- \( y_1, y_2, y_3, y_4 \) numbers in (3, 12.5) with mean 7.5 and sdev 2.03

Source

References

Examples

```r
require(stats); require(graphics)
summary(anscombe)
```

###-- now some "magic" to do the 4 regressions in a loop:

```r
ff <- y ~ x
mods <- setNames(as.list(1:4), paste0("lm", 1:4))
for(i in 1:4) {
  ff[2:3] <- lapply(paste0(c("y","x"), i), as.name)
  ## or  ff[[2]] <- as.name(paste0("y", i))
  ## ff[[3]] <- as.name(paste0("x", i))
  mods[[i]] <- lmi <- lm(ff, data = anscombe)
  print(anova(lmi))
```
attenu

The Joyner–Boore Attenuation Data

Description

This data gives peak accelerations measured at various observation stations for 23 earthquakes in California. The data have been used by various workers to estimate the attenuating affect of distance on ground acceleration.

Usage

attenu

Format

A data frame with 182 observations on 5 variables.

austres  
**Quarterly Time Series of the Number of Australian Residents**

**Description**

Numbers (in thousands) of Australian residents measured quarterly from March 1971 to March 1994. The object is of class "ts".

**Usage**

austres

**Source**

beavers  
**Body Temperature Series of Two Beavers**

**Description**

Reynolds (1994) describes a small part of a study of the long-term temperature dynamics of beaver *Castor canadensis* in north-central Wisconsin. Body temperature was measured by telemetry every 10 minutes for four females, but data from a one period of less than a day for each of two animals is used there.

**Usage**

beaver1
beaver2
Format

The `beaver1` data frame has 114 rows and 4 columns on body temperature measurements at 10 minute intervals.

The `beaver2` data frame has 100 rows and 4 columns on body temperature measurements at 10 minute intervals.

The variables are as follows:

- **day** Day of observation (in days since the beginning of 1990), December 12–13 (`beaver1`) and November 3–4 (`beaver2`).
- **time** Time of observation, in the form 0330 for 3:30am
- **temp** Measured body temperature in degrees Celsius.
- **activ** Indicator of activity outside the retreat.

Note

The observation at 22:20 is missing in `beaver1`.

Source

Examples

```r
require(graphics)
(yl <- range(beaver1$temp, beaver2$temp))

beaver.plot <- function(bdat, ...) {
  nam <- deparse(substitute(bdat))
  with(bdat, {
    # Hours since start of day:
    hours <- time %/% 100 + 24*(day - day[1]) + (time %% 100)/60
    plot(hours, temp, type = "l", ...,
         main = paste(nam, "body temperature"))
    abline(h = 37.5, col = "gray", lty = 2)
    is.act <- activ == 1
    points(hours[is.act], temp[is.act], col = 2, cex = .8)
  })
}

op <- par(mfrow = c(2, 1), mar = c(3, 3, 4, 2), mgp = 0.9 * 2:0)
beaver.plot(beaver1, ylim = yl)
beaver.plot(beaver2, ylim = yl)
par(op)
```
BJsales  

Sales Data with Leading Indicator

Description

The sales time series BJsales and leading indicator BJsales.lead each contain 150 observations. The objects are of class "ts".

Usage

BJsales
BJsales.lead

Source

The data are given in Box & Jenkins (1976). Obtained from the Time Series Data Library at [https://robjhyndman.com/TSDL/](https://robjhyndman.com/TSDL/)

BOD  

Biochemical Oxygen Demand

Description

The BOD data frame has 6 rows and 2 columns giving the biochemical oxygen demand versus time in an evaluation of water quality.

Usage

BOD

Format

This data frame contains the following columns:

- Time  A numeric vector giving the time of the measurement (days).
- demand  A numeric vector giving the biochemical oxygen demand (mg/l).

Source

Examples

```r
require(stats)
# simplest form of fitting a first-order model to these data
fm1 <- nls(demand ~ A*(1-exp(-exp(lrc)*Time)), data = BOD,
           start = c(A = 20, lrc = log(.35)))
coef(fm1)
fml
# using the plinear algorithm (trace o/p differs by platform)
## IGNORE_RDIFF_BEGIN
fm2 <- nls(demand ~ (1-exp(-exp(lrc)*Time)), data = BOD,
           start = c(lrc = log(.35)), algorithm = "plinear", trace = TRUE)
## IGNORE_RDIFF_END
# using a self-starting model
fm3 <- nls(demand ~ SSasympOrig(Time, A, lrc), data = BOD)
summary(fm3)
```

Cars

### Speed and Stopping Distances of Cars

**Description**

The data give the speed of cars and the distances taken to stop. Note that the data were recorded in the 1920s.

**Usage**

cars

**Format**

A data frame with 50 observations on 2 variables.

```
[,1] speed numeric Speed (mph)
[,2] dist numeric Stopping distance (ft)
```

**Source**

**References**

ChickWeight

Weight versus age of chicks on different diets

Description

The ChickWeight data frame has 578 rows and 4 columns from an experiment on the effect of diet on early growth of chicks.

Usage

ChickWeight

Format

An object of class c("nfnGroupedData","nfGroupedData","groupedData","data.frame") containing the following columns:

weight a numeric vector giving the body weight of the chick (gm).
Time a numeric vector giving the number of days since birth when the measurement was made.
Chick an ordered factor with levels 18 < ... < 48 giving a unique identifier for the chick. The ordering of the levels groups chicks on the same diet together and orders them according to their final weight (lightest to heaviest) within diet.
Diet a factor with levels 1, ..., 4 indicating which experimental diet the chick received.

Details

The body weights of the chicks were measured at birth and every second day thereafter until day 20. They were also measured on day 21. There were four groups on chicks on different protein diets.

This dataset was originally part of package nlme, and that has methods (including for [, as.data.frame, plot and print) for its grouped-data classes.
chickwts 667

Source

SSlogis for models fitted to this dataset.

Examples
```r
require(graphics)
coplot(weight ~ Time | Chick, data = ChickWeight, type = "b", show.given = FALSE)
```

<table>
<thead>
<tr>
<th>chickwts</th>
<th>Chicken Weights by Feed Type</th>
</tr>
</thead>
</table>

Description
An experiment was conducted to measure and compare the effectiveness of various feed supplements on the growth rate of chickens.

Usage
```r
chickwts
```

Format
A data frame with 71 observations on the following 2 variables.

<table>
<thead>
<tr>
<th>weight</th>
<th>a numeric variable giving the chick weight.</th>
</tr>
</thead>
<tbody>
<tr>
<td>feed</td>
<td>a factor giving the feed type.</td>
</tr>
</tbody>
</table>

Details
Newly hatched chicks were randomly allocated into six groups, and each group was given a different feed supplement. Their weights in grams after six weeks are given along with feed types.

Source

Examples

```r
require(stats); require(graphics)
boxplot(weight ~ feed, data = chickwts, col = "lightgray",
        varwidth = TRUE, notch = TRUE, main = "chickwt data",
        ylab = "Weight at six weeks (gm")
anova(fm1 <- lm(weight ~ feed, data = chickwts))
opar <- par(mfrow = c(2, 2), oma = c(0, 0, 1.1, 0),
        mar = c(4.1, 4.1, 2.1, 1.1))
plot(fm1)
par(opar)
```

Carbon Dioxide Uptake in Grass Plants

Description

The CO2 data frame has 84 rows and 5 columns of data from an experiment on the cold tolerance of the grass species *Echinochloa crus-galli*.

Usage

CO2

Format

An object of class c("nfnGroupedData","nfgroupedData","groupedData","data.frame") containing the following columns:

- **Plant** an ordered factor with levels Qn1 < Qn2 < Qn3 < ... < Mc1 giving a unique identifier for each plant.
- **Type** a factor with levels Quebec Mississippi giving the origin of the plant
- **Treatment** a factor with levels nonchilled chilled
- **conc** a numeric vector of ambient carbon dioxide concentrations (mL/L).
- **uptake** a numeric vector of carbon dioxide uptake rates (µmol/m² sec).

Details

The CO₂ uptake of six plants from Quebec and six plants from Mississippi was measured at several levels of ambient CO₂ concentration. Half the plants of each type were chilled overnight before the experiment was conducted.

This dataset was originally part of package nlme, and that has methods (including for [, as.data.frame, plot and print) for its grouped-data classes.

Source

Examples

```r
require(stats); require(graphics)

coplot(uptake ~ conc | Plant, data = CO2, show.given = FALSE, type = "b")
## fit the data for the first plant
fm1 <- nls(uptake ~ SSasymp(conc, Asym, lrc, c0),
  data = CO2, subset = Plant == "Qn1")
summary(fm1)
## fit each plant separately
fmlist <- list()
for (pp in levels(CO2$Plant)) {
  fmlist[[pp]] <- nls(uptake ~ SSasymp(conc, Asym, lrc, c0),
    data = CO2, subset = Plant == pp)
}
## check the coefficients by plant
print(sapply(fmlist, coef), digits = 3)
```

---

**Description**

Atmospheric concentrations of CO₂ are expressed in parts per million (ppm) and reported in the preliminary 1997 SIO manometric mole fraction scale.

**Usage**

c02

**Format**

A time series of 468 observations; monthly from 1959 to 1997.

**Details**

The values for February, March and April of 1964 were missing and have been obtained by interpolating linearly between the values for January and May of 1964.

**Source**

Keeling, C. D. and Whorf, T. P., Scripps Institution of Oceanography (SIO), University of California, La Jolla, California USA 92093-0220.

**References**

**Examples**

```r
require(graphics)
plot(co2, ylab = expression("Atmospheric concentration of CO"[2]),
  las = 1)
title(main = "co2 data set")
```
Description

Data of 3000 male criminals over 20 years old undergoing their sentences in the chief prisons of England and Wales.

Usage

crimtab

Format

A table object of integer counts, of dimension 42 × 22 with a total count, sum(crimtab) of 3000. The 42 rownames ("9.4", "9.5", ...) correspond to midpoints of intervals of finger lengths whereas the 22 column names (colnames) ("142.24", "144.78", ...) correspond to (body) heights of 3000 criminals, see also below.

Details

Student is the pseudonym of William Sealy Gosset. In his 1908 paper he wrote (on page 13) at the beginning of section VI entitled Practical Test of the foregoing Equations:

"Before I had succeeded in solving my problem analytically, I had endeavoured to do so empirically. The material used was a correlation table containing the height and left middle finger measurements of 3000 criminals, from a paper by W. R. MacDonell (Biometrika, Vol. I., p. 219). The measurements were written out on 3000 pieces of cardboard, which were then very thoroughly shuffled and drawn at random. As each card was drawn its numbers were written down in a book, which thus contains the measurements of 3000 criminals in a random order. Finally, each consecutive set of 4 was taken as a sample—750 in all—and the mean, standard deviation, and correlation of each sample determined. The difference between the mean of each sample and the mean of the population was then divided by the standard deviation of the sample, giving us the $z$ of Section III."

The table is in fact page 216 and not page 219 in MacDonell(1902). In the MacDonell table, the middle finger lengths were given in mm and the heights in feet/inches intervals, they are both converted into cm here. The midpoints of intervals were used, e.g., where MacDonell has $4'7''9/16 - 8''9/16$, we have $142.24$ which is $2.54 \times 56 = 2.54 \times (4'8'').$

MacDonell credited the source of data (page 178) as follows: The data on which the memoir is based were obtained, through the kindness of Dr Garson, from the Central Metric Office, New Scotland Yard... He pointed out on page 179 that: The forms were drawn at random from the mass on the office shelves; we are therefore dealing with a random sampling.

Source

References

Examples

```r
require(stats)
dim(crimtab)
utils::str(crimtab)
## for nicer printing:
local({
cT <- crimtab
columns(cT) <- substring(columns(cT), 2, 3)
print(cT, zero.print = " ")
})

## Repeat Student's experiment:

# 1) Reconstitute 3000 raw data for heights in inches and rounded to
# nearest integer as in Student’s paper:
(heIn <- round(as.numeric(columns(crimtab)) / 2.54))
d.hei <- data.frame(height = rep(heIn, colSums(crimtab)))

# 2) shuffle the data:
set.seed(1)
d.hei <- d.hei[sample(1:3000), , drop = FALSE]

# 3) Make 750 samples each of size 4:
d.hei$sample <- as.factor(rep(1:750, each = 4))

# 4) Compute the means and standard deviations (n) for the 750 samples:

h.mean <- with(d.hei, tapply(height, sample, FUN = mean))

h.sd <- with(d.hei, tapply(height, sample, FUN = sd)) * sqrt(3/4)

# 5) Compute the difference between the mean of each sample and
# the mean of the population and then divide by the
# standard deviation of the sample:

zobs <- (h.mean - mean(d.hei[, "height"]))/h.sd

# 6) Replace infinite values by +/- 6 as in Student's paper:

zobs[infZ <- is.infinite(zobs)] # none of them

zobs[infZ] <- 6 * sign(zobs[infZ])

# 7) Plot the distribution:

require(grDevices); require(graphics)
```
DNase

Elisa assay of DNase

Description

The DNase data frame has 176 rows and 3 columns of data obtained during development of an ELISA assay for the recombinant protein DNase in rat serum.

Usage

DNase

discoveries

Yearly Numbers of Important Discoveries

Description

The numbers of "great" inventions and scientific discoveries in each year from 1860 to 1959.

Usage

discoveries

Format

A time series of 100 values.

Source

References

Examples

require(graphics)
plot(discoveries, ylab = "Number of important discoveries",
    las = 1)
title(main = "discoveries data set")
Format

An object of class c("nfnGroupedData","nfGroupedData","groupedData","data.frame") containing the following columns:

- **Run** an ordered factor with levels 10 < ... < 3 indicating the assay run.
- **conc** a numeric vector giving the known concentration of the protein.
- **density** a numeric vector giving the measured optical density (dimensionless) in the assay. Duplicate optical density measurements were obtained.

Details

This dataset was originally part of package nlme, and that has methods (including for [, as.data.frame, plot and print) for its grouped-data classes.

Source

ttt[ttt == 1] <- esoph$ncases[o]
tt1 <- table(esoph$agegp, esoph$alcgp, esoph$tobgp)
tt1[tt1 == 1] <- esoph$ncontrols[o]
tt <- array(c(ttt, tt1), c(dim(ttt),2),
    c(dimnames(ttt), list(c("Cancer", "control"))))
mosaicplot(tt, main = "esoph data set", color = TRUE)
```
Description

Conversion rates between the various Euro currencies.

Usage

euro
euro.cross

Format

euro is a named vector of length 11, euro.cross a matrix of size 11 by 11, with dimnames.

Details

The data set euro contains the value of 1 Euro in all currencies participating in the European monetary union (Austrian Schilling ATS, Belgian Franc BEF, German Mark DEM, Spanish Peseta ESP, Finnish Markka FIM, French Franc FRF, Irish Punt IEP, Italian Lira ITL, Luxembourg Franc LUF, Dutch Guilder NLG and Portuguese Escudo PTE). These conversion rates were fixed by the European Union on December 31, 1998. To convert old prices to Euro prices, divide by the respective rate and round to 2 digits.

The data set euro.cross contains conversion rates between the various Euro currencies, i.e., the result of outer(1 / euro, euro).

Examples

cbind(euro)

## These relations hold:
euro == signif(euro, 6) # [6 digit precision in Euro's definition]
all(euro.cross == outer(1/euro, euro))

## Convert 20 Euro to Belgian Franc
20 * euro["BEF"]

## Convert 20 Austrian Schilling to Euro
20 / euro["ATS"]

## Convert 20 Spanish Pesetas to Italian Lira
20 * euro.cross["ESP", "ITL"]

require(graphics)
dotchart(euro,
  main = "euro data: 1 Euro in currency unit")
dotchart(1/euro,
  main = "euro data: 1 currency unit in Euros")
dotchart(log(euro, 10),
  main = "euro data: log10(1 Euro in currency unit)")
eurowdist

_Distances Between European Cities and Between US Cities_

**Description**

The `eurowdist` gives the road distances (in km) between 21 cities in Europe. The data are taken from a table in *The Cambridge Encyclopaedia*. `UScitiesD` gives “straight line” distances between 10 cities in the US.

**Usage**

eurowdist

**Format**

dist objects based on 21 and 10 objects, respectively. (You must have the `stats` package loaded to have the methods for this kind of object available).

**Source**

---

EuStockMarkets

_Daily Closing Prices of Major European Stock Indices, 1991–1998_

**Description**

Contains the daily closing prices of major European stock indices: Germany DAX (Ibis), Switzerland SMI, France CAC, and UK FTSE. The data are sampled in business time, i.e., weekends and holidays are omitted.

**Usage**

EuStockMarkets

**Format**

A multivariate time series with 1860 observations on 4 variables. The object is of class "mts".

**Source**

The data were kindly provided by Erste Bank AG, Vienna, Austria.
Old Faithful Geyser Data

Description

Waiting time between eruptions and the duration of the eruption for the Old Faithful geyser in Yellowstone National Park, Wyoming, USA.

Usage

faithful

Format

A data frame with 272 observations on 2 variables.

<table>
<thead>
<tr>
<th></th>
<th>eruptions</th>
<th>numeric</th>
<th>waiting</th>
<th>numeric</th>
</tr>
</thead>
<tbody>
<tr>
<td>.1</td>
<td>Eruption</td>
<td>mins</td>
<td></td>
<td>mins</td>
</tr>
<tr>
<td>.2</td>
<td>Waiting</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Details

A closer look at faithful$eruptions reveals that these are heavily rounded times originally in seconds, where multiples of 5 are more frequent than expected under non-human measurement. For a better version of the eruption times, see the example below.

There are many versions of this dataset around: Azzalini and Bowman (1990) use a more complete version.

Source

W. Härdle.

References

See Also

geyer in package MASS for the Azzalini–Bowman version.

Examples

```r
require(stats); require(graphics)

f.tit <- "faithful data: Eruptions of Old Faithful"

ne60 <- round(e60 <- 60 * faithful$eruptions)
all.equal(e60, ne60)  # relative diff. ~ 1/10000

table(zapsmall(abs(e60 - ne60)))  # 0, 0.02 or 0.04

faithful$better.eruptions <- ne60 / 60

tv <- table(ne60)
```
Determination of Formaldehyde

Description

These data are from a chemical experiment to prepare a standard curve for the determination of formaldehyde by the addition of chromatropic acid and concentrated sulphuric acid and the reading of the resulting purple color on a spectrophotometer.

Usage

Formaldehyde

Format

A data frame with 6 observations on 2 variables.

\[
\begin{array}{cc}
[.1] & \text{Carbohydrate (ml)} \\
[.2] & \text{Optical Density}
\end{array}
\]

Source

References

Examples

```r
require(stats); require(graphics)
plot(optden ~ carb, data = Formaldehyde,
     xlab = "Carbohydrate (ml)", ylab = "Optical Density",
     main = "Formaldehyde data", col = 4, las = 1)
abline(fm1 <- lm(optden ~ carb, data = Formaldehyde))
summary(fm1)
par(opar <- par(mfrow = c(2, 2), oma = c(0, 0, 1.1, 0))
plot(fm1)
par(opar)
```
**Description**

Freeny’s data on quarterly revenue and explanatory variables.

**Usage**

```r
freeny
freeny.x
freeny.y
```

**Format**

There are three ‘freeny’ data sets.

- `freeny.y` is a time series with 39 observations on quarterly revenue from (1962.2Q) to (1971.4Q).
- `freeny.x` is a matrix of explanatory variables. The columns are `freeny.y` lagged 1 quarter, price index, income level, and market potential.
- Finally, `freeny` is a data frame with variables `y`, `lag.quarterly.revenue`, `price.index`, `income.level`, and `market.potential` obtained from the above two data objects.

**Source**

**References**

**Examples**

```r
require(stats); require(graphics)
summary(freeny)
pairs(freeny, main = "freeny data")
# gives warning: freeny$y has class "ts"

summary(fm1 <- lm(y ~ ., data = freeny))
opar <- par(mfrow = c(2, 2), oma = c(0, 0, 1.1, 0),
          mar = c(4.1, 4.1, 2.1, 1.1))
plot(fm1)
par(opar)
```
**Description**

Distribution of hair and eye color and sex in 592 statistics students.

**Usage**

HairEyeColor

**Format**

A 3-dimensional array resulting from cross-tabulating 592 observations on 3 variables. The variables and their levels are as follows:

<table>
<thead>
<tr>
<th>No</th>
<th>Name</th>
<th>Levels</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Hair</td>
<td>Black, Brown, Red, Blond</td>
</tr>
<tr>
<td>2</td>
<td>Eye</td>
<td>Brown, Blue, Hazel, Green</td>
</tr>
<tr>
<td>3</td>
<td>Sex</td>
<td>Male, Female</td>
</tr>
</tbody>
</table>

**Details**

The Hair \( \times \) Eye table comes from a survey of students at the University of Delaware reported by Snee (1974). The split by Sex was added by Friendly (1992a) for didactic purposes.

This data set is useful for illustrating various techniques for the analysis of contingency tables, such as the standard chi-squared test or, more generally, log-linear modelling, and graphical methods such as mosaic plots, sieve diagrams or association plots.

**Source**

[http://www.datavis.ca/sas/vcd/catdata/haireye.sas](http://www.datavis.ca/sas/vcd/catdata/haireye.sas)

Snee (1974) gives the two-way table aggregated over Sex. The Sex split of the ‘Brown hair, Brown eye’ cell was changed to agree with that used by Friendly (2000).

**Indometh**  
*Pharmacokinetics of Indomethacin*

Description

The Indometh data frame has 66 rows and 3 columns of data on the pharmacokinetics of indomethacin (or, older spelling, ‘indomethacin’).

Usage

Indometh

Format

An object of class c("nfnGroupedData","nfGroupedData","groupedData","data.frame") containing the following columns:

- **Subject** an ordered factor with containing the subject codes. The ordering is according to increasing maximum response.
- **time** a numeric vector of times at which blood samples were drawn (hr).
- **conc** a numeric vector of plasma concentrations of indomethacin (mcg/ml).

Details

Each of the six subjects were given an intravenous injection of indomethacin.

This dataset was originally part of package nlme, and that has methods (including for [, as.data.frame, plot and print) for its grouped-data classes.

iris    Edgar Anderson’s Iris Data
Description

This famous (Fisher’s or Anderson’s) iris data set gives the measurements in centimeters of the variables sepal length and width and petal length and width, respectively, for 50 flowers from each of 3 species of iris. The species are Iris setosa, versicolor, and virginica.

Usage

iris
iris3

Format

iris is a data frame with 150 cases (rows) and 5 variables (columns) named Sepal.Length, Sepal.Width, Petal.Length, Petal.Width, and Species.

iris3 gives the same data arranged as a 3-dimensional array of size 50 by 4 by 3, as represented by S-PLUS. The first dimension gives the case number within the species subsample, the second the measurements with names Sepal L., Sepal W., Petal L., and Petal W., and the third the species.

LifeCycleSavings

Description

Usage

LifeCycleSavings

Format

A data frame with 50 observations on 5 variables.

[,1] sr numeric aggregate personal savings
[,2] pop15 numeric % of population under 15
[,3] pop75 numeric % of population over 75
[,4] dpi numeric real per-capita disposable income
[,5] ddpi numeric % growth rate of dpi

Details

Under the life-cycle savings hypothesis as developed by Franco Modigliani, the savings ratio (aggregate personal saving divided by disposable income) is explained by per-capita disposable income, the percentage rate of change in per-capita disposable income, and two demographic variables: the percentage of population less than 15 years old and the percentage of the population over 75 years old. The data are averaged over the decade 1960–1970 to remove the business cycle or other short-term fluctuations.

Source

The data were obtained from Belsley, Kuh and Welsch (1980). They in turn obtained the data from Sterling (1977).

Longley's Economic Regression Data

Description

A macroeconomic data set which provides a well-known example for a highly collinear regression.

Usage

longley

Format

A data frame with 7 economical variables, observed yearly from 1947 to 1962 ($n = 16$).

- **GNP.deflator**: GNP implicit price deflator ($1954 = 100$)
- **GNP**: Gross National Product.
- **Unemployed**: number of unemployed.
- **Armed.Forces**: number of people in the armed forces.
- **Population**: ‘noninstitutionalized’ population ≥ 14 years of age.
- **Year**: the year (time).
- **Employed**: number of people employed.

The regression `lm(Employed ~ .)` is known to be highly collinear.

Source

References

Examples

```r
require(stats); require(graphics)
## give the data set in the form it is used in S-PLUS:
longley.x <- data.matrix(longley[, 1:6])
longley.y <- longley[, "Employed"]
pairs(longley, main = "longley data")
summary(fm1 <- lm(Employed ~ ., data = longley))
opar <- par(mfrow = c(2, 2), oma = c(0, 0, 1.1, 0),
         mar = c(4.1, 4.1, 2.1, 1.1))
plot(fm1)
par(opar)
```
**lynx**

*Annual Canadian Lynx trappings 1821–1934*

**Description**

Annual numbers of lynx trappings for 1821–1934 in Canada. Taken from Brockwell & Davis (1991), this appears to be the series considered by Campbell & Walker (1977).

**Usage**

lynx

**Source**

**References**

**morley**

*Michelson Speed of Light Data*

**Description**

A classical data of Michelson (but not this one with Morley) on measurements done in 1879 on the speed of light. The data consists of five experiments, each consisting of 20 consecutive ‘runs’. The response is the speed of light measurement, suitably coded (km/sec, with 299000 subtracted).

**Usage**

morley

**Format**

A data frame with 100 observations on the following 3 variables.

- **Expt** The experiment number, from 1 to 5.
- **Run** The run number within each experiment.
- **Speed** Speed-of-light measurement.

**Details**

The data is here viewed as a randomized block experiment with ‘experiment’ and ‘run’ as the factors. ‘run’ may also be considered a quantitative variate to account for linear (or polynomial) changes in the measurement over the course of a single experiment.
Note

This is the same dataset as michelson in package MASS.

Source

A. A. Michelson (1882) Experimental determination of the velocity of light made at the United States Naval Academy, Annapolis. *Astronomic Papers* 1 135–8. U.S. Nautical Almanac Office. (See Table 24.)

Examples

```r
require(stats); require(graphics)
michelson <- transform(morley,
    Expt = factor(Expt), Run = factor(Run))
xtabs(~ Expt + Run, data = michelson) # 5 x 20 balanced (two-way)
plot(Speed ~ Expt, data = michelson,
    main = "Speed of Light Data", xlab = "Experiment No.")
fm <- aov(Speed ~ Run + Expt, data = michelson)
summary(fm)
fm0 <- update(fm, . ~ . - Run)
anova(fm0, fm)
```

mtcars

*Motor Trend Car Road Tests*

Description

The data was extracted from the 1974 *Motor Trend* US magazine, and comprises fuel consumption and 10 aspects of automobile design and performance for 32 automobiles (1973–74 models).

Usage

mtcars

Format

A data frame with 32 observations on 11 (numeric) variables.

- [.1] mpg  Miles/(US) gallon
- [.2] cyl  Number of cylinders
- [.3] disp Displacement (cu.in.)
- [.4] hp  Gross horsepower
- [.5] drat Rear axle ratio
- [.6] wt  Weight (1000 lbs)
- [.7] qsec 1/4 mile time
- [.8] vs  Engine (0 = V-shaped, 1 = straight)
- [.9] am Transmission (0 = automatic, 1 = manual)
- [.10] gear Number of forward gears
- [.11] carb Number of carburetors
Henderson and Velleman (1981) comment in a footnote to Table 1: ‘Hocking [original transcriber]’s noncrucial coding of the Mazda’s rotary engine as a straight six-cylinder engine and the Porsche’s flat engine as a V engine, as well as the inclusion of the diesel Mercedes 240D, have been retained to enable direct comparisons to be made with previous analyses.’

**Source**

**Examples**

```r
require(graphics)
pairs(mtcars, main = "mtcars data", gap = 1/4)
coplot(mpg ~ disp | as.factor(cyl), data = mtcars,
       panel = panel.smooth, rows = 1)
## possibly more meaningful, e.g., for summary() or bivariate plots:
mtcars2 <- within(mtcars, {
    vs <- factor(vs, labels = c("V", "S"))
    am <- factor(am, labels = c("automatic", "manual"))
    cyl <- ordered(cyl)
    gear <- ordered(gear)
    carb <- ordered(carb)
})
summary(mtcars2)
```

### nhtemp

**Average Yearly Temperatures in New Haven**

**Description**

The mean annual temperature in degrees Fahrenheit in New Haven, Connecticut, from 1912 to 1971.

**Usage**

```r
nhtemp
```

**Format**

A time series of 60 observations.

**Source**

**References**

Examples

```r
require(stats); require(graphics)
plot(nhtemp, main = "nhtemp data",
     ylab = "Mean annual temperature in New Haven, CT (deg. F)")
```

---

**Nile**  

**Flow of the River Nile**

**Description**

Measurements of the annual flow of the river Nile at Aswan (formerly Assuan), 1871–1970, in $10^8 m^3$, “with apparent changepoint near 1898” (Cobb(1978), Table 1, p.249).

**Usage**

Nile

**Format**

A time series of length 100.

**Source**

**References**

**Examples**

```r
require(stats); require(graphics)
par(mfrow = c(2, 2))
plot(Nile)
acf(Nile)
pacf(Nile)
ar(Nile) # selects order 2
cpgram(ar(Nile)$resid)
par(mfrow = c(1, 1))
arima(Nile, c(2, 0, 0))

## Now consider missing values, following Durbin & Koopman
NileNA <- Nile
NileNA[c(21:40, 61:80)] <- NA
arima(NileNA, c(2, 0, 0))
plot(NileNA)
pred <-
  predict(arima(window(NileNA, 1871, 1890), c(2, 0, 0)), n.ahead = 20)
lines(pred$pred, lty = 3, col = "red")
```
lines(pred$pred + 2*pred$se, lty = 2, col = "blue")
lines(pred$pred - 2*pred$se, lty = 2, col = "blue")
pred <-
  predict(arima(window(NileNA, 1871, 1930), c(2, 0, 0)), n.ahead = 20)
lines(pred$pred, lty = 3, col = "red")
lines(pred$pred + 2*pred$se, lty = 2, col = "blue")
lines(pred$pred - 2*pred$se, lty = 2, col = "blue")

## Structural time series models
par(mfrow = c(3, 1))
plot(Nile)
## local level model
(fit <- StructTS(Nile, type = "level"))
lines(fitted(fit), lty = 2)  # contemporaneous smoothing
lines(tsSmooth(fit), lty = 2, col = 4)  # fixed-interval smoothing
plot(residuals(fit)); abline(h = 0, lty = 3)
## local trend model
(fit2 <- StructTS(Nile, type = "trend"))  ## constant trend fitted
pred <- predict(fit, n.ahead = 30)
## with 50% confidence interval
t.s.plot(Nile, pred$pred,
  pred$pred + 0.67*pred$se, pred$pred -0.67*pred$se)

## Now consider missing values
plot(NileNA)
(fit3 <- StructTS(NileNA, type = "level"))
lines(fitted(fit3), lty = 2)
lines(tsSmooth(fit3), lty = 3)
plot(residuals(fit3)); abline(h = 0, lty = 3)

nottem

nottem

<table>
<thead>
<tr>
<th>Average Monthly Temperatures at Nottingham, 1920–1939</th>
</tr>
</thead>
</table>

Description

A time series object containing average air temperatures at Nottingham Castle in degrees Fahrenheit for 20 years.

Usage

nottem

Source

Examples

```
require(stats); require(graphics)
nott <- window(nottem, end = c(1936,12))
fit <- arima(nott, order = c(1,0,0), list(order = c(2,1,0), period = 12))
nott.fore <- predict(fit, n.ahead = 36)
t.s.plot(nott, nott.fore$pred, nott.fore$pred+2*nott.fore$se, nott.fore$pred-2*nott.fore$se, gpars = list(col = c(1,1,4,4)))
```
Description

A classical N, P, K (nitrogen, phosphate, potassium) factorial experiment on the growth of peas conducted on 6 blocks. Each half of a fractional factorial design confounding the NPK interaction was used on 3 of the plots.

Usage

npk

Format

The npk data frame has 24 rows and 5 columns:

block which block (label 1 to 6).
N indicator (0/1) for the application of nitrogen.
P indicator (0/1) for the application of phosphate.
K indicator (0/1) for the application of potassium.
yield Yield of peas, in pounds/plot (the plots were (1/70) acre).

Source

References

Examples

options(contrasts = c("contr.sum", "contr.poly"))
npk.aov <- aov(yield ~ block + N*P*K, npk)
summary(npk.aov)
coef(npk.aov)
options(contrasts = c("contr.treatment", "contr.poly"))
npk.aov1 <- aov(yield ~ block + N + K, data = npk)
summary.lm(npk.aov1)
se.contrast(npk.aov1, list(N=="0", N=="1"), data = npk)
model.tables(npk.aov1, type = "means", se = TRUE)
occupationalStatus

Description

Cross-classification of a sample of British males according to each subject’s occupational status and his father’s occupational status.

Usage

occupationalStatus

Format

A table of counts, with classifying factors origin (father’s occupational status; levels 1:8) and destination (son’s occupational status; levels 1:8).

Source

The data set has been in package gnm and been provided by the package authors.

Examples

require(stats); require(graphics)

plot(occupationalStatus)

## Fit a uniform association model separating diagonal effects
Diag <- as.factor(diag(1:8))
Rscore <- scale(as.numeric(row(occupationalStatus)), scale = FALSE)
Cscore <- scale(as.numeric(col(occupationalStatus)), scale = FALSE)
modUnif <- glm(Freq ~ origin + destination + Diag + Rscore:Cscore,
               family = poisson, data = occupationalStatus)

summary(modUnif)
plot(modUnif) # 4 plots, with warning about h_ii ~ 1

Orange

Description

The Orange data frame has 35 rows and 3 columns of records of the growth of orange trees.

Usage

Orange
OrchardSprays

Format

An object of class c("nfnGroupedData", "nfGroupedData", "groupedData", "data.frame") containing the following columns:

**Tree** an ordered factor indicating the tree on which the measurement is made. The ordering is according to increasing maximum diameter.

**age** a numeric vector giving the age of the tree (days since 1968/12/31)

**circumference** a numeric vector of trunk circumferences (mm). This is probably “circumference at breast height”, a standard measurement in forestry.

Details

This dataset was originally part of package nlme, and that has methods (including for [], as.data.frame, plot and print) for its grouped-data classes.

Source

Examples

```r
require(stats); require(graphics)
coplot(circumference ~ age | Tree, data = Orange, show.given = FALSE)
fm1 <- nls(circumference ~ SSlogis(age, Asym, xmid, scal),
    data = Orange, subset = Tree == 3)
plot(circumference ~ age, data = Orange, subset = Tree == 3,
    xlab = "Tree age (days since 1968/12/31)",
    ylab = "Tree circumference (mm)", las = 1,
    main = "Orange tree data and fitted model (Tree 3 only)")
age <- seq(0, 1600, length.out = 101)
lines(age, predict(fm1, list(age = age)))
```

---

**OrchardSprays**

*Potency of Orchard Sprays*

Description

An experiment was conducted to assess the potency of various constituents of orchard sprays in repelling honeybees, using a Latin square design.

Usage

OrchardSprays

Format

A data frame with 64 observations on 4 variables.

```r
[1,] rowpos   numeric Row of the design
[2,] colpos   numeric Column of the design
[3,] treatment factor Treatment level
[4,] decrease  numeric Response
```
Individual cells of dry comb were filled with measured amounts of lime sulphur emulsion in sucrose solution. Seven different concentrations of lime sulphur ranging from a concentration of 1/100 to 1/1,562,500 in successive factors of 1/5 were used as well as a solution containing no lime sulphur. The responses for the different solutions were obtained by releasing 100 bees into the chamber for two hours, and then measuring the decrease in volume of the solutions in the various cells.

An $8 \times 8$ Latin square design was used and the treatments were coded as follows:

- **A**: highest level of lime sulphur
- **B**: next highest level of lime sulphur
- ...
- **G**: lowest level of lime sulphur
- **H**: no lime sulphur

**Source**

**References**

**Examples**

```r
require(graphics)
pairs(OrchardSprays, main = "OrchardSprays data")
```

**Description**

Results from an experiment to compare yields (as measured by dried weight of plants) obtained under a control and two different treatment conditions.

**Usage**

`PlantGrowth`

**Format**

A data frame of 30 cases on 2 variables.

```
[, 1]  weight  numeric
[, 2]  group  factor
```

The levels of group are ‘ctrl’, ‘trt1’, and ‘trt2’.
### Examples

```r
## One factor ANOVA example from Dobson's book, cf. Table 7.4:
require(stats); require(graphics)
boxplot(weight ~ group, data = PlantGrowth, main = "PlantGrowth data",
        ylab = "Dried weight of plants", col = "lightgray",
        notch = TRUE, varwidth = TRUE)
anova(lm(weight ~ group, data = PlantGrowth))
```

require(stats); require(graphics)
plot(presidents, las = 1, ylab = "Approval rating (%)",
     main = "presidents data")
```

pressure

**Vapor Pressure of Mercury as a Function of Temperature**

**Description**

Data on the relation between temperature in degrees Celsius and vapor pressure of mercury in millimeters (of mercury).

**Usage**

pressure

**Format**

A data frame with 19 observations on 2 variables.
Puromycin

Reaction Velocity of an Enzymatic Reaction

Description

The Puromycin data frame has 23 rows and 3 columns of the reaction velocity versus substrate concentration in an enzymatic reaction involving untreated cells or cells treated with Puromycin.

Usage

Puromycin

Format

This data frame contains the following columns:

conc  a numeric vector of substrate concentrations (ppm)
rate  a numeric vector of instantaneous reaction rates (counts/min/min)
state  a factor with levels treated untreated

Details

Data on the velocity of an enzymatic reaction were obtained by Treloar (1974). The number of counts per minute of radioactive product from the reaction was measured as a function of substrate concentration in parts per million (ppm) and from these counts the initial rate (or velocity) of the reaction was calculated (counts/min/min). The experiment was conducted once with the enzyme treated with Puromycin, and once with the enzyme untreated.
Source

See Also

`SSmicmen` for other models fitted to this dataset.

Examples

```r
require(stats); require(graphics)

plot(rate ~ conc, data = Puromycin, las = 1,
     xlab = "Substrate concentration (ppm)",
     ylab = "Reaction velocity (counts/min/min)",
     pch = as.integer(Puromycin$state),
     col = as.integer(Puromycin$state),
     main = "Puromycin data and fitted Michaelis-Menten curves")
## simplest form of fitting the Michaelis-Menten model to these data
fm1 <- nls(rate ~ Vm * conc/(K + conc), data = Puromycin,
            subset = state == "treated",
            start = c(Vm = 200, K = 0.05))
fm2 <- nls(rate ~ Vm * conc/(K + conc), data = Puromycin,
            subset = state == "untreated",
            start = c(Vm = 100, K = 0.05))
summary(fm1)
summary(fm2)
## add fitted lines to the plot
conc <- seq(0, 1.2, length.out = 101)
lines(conc, predict(fm1, list(conc = conc)), lty = 1, col = 1)
lines(conc, predict(fm2, list(conc = conc)), lty = 2, col = 2)
legend(0.8, 120, levels(Puromycin$state),
       col = 1:2, lty = 1:2, pch = 1:2)
## using partial linearity
fm3 <- nls(rate ~ conc/(K + conc), data = Puromycin,
            subset = state == "treated", start = c(K = 0.05),
            algorithm = "plinear")
```

---

**quakes**

*Locations of Earthquakes off Fiji*

**Description**

The data set give the locations of 1000 seismic events of MB > 4.0. The events occurred in a cube near Fiji since 1964.

**Usage**

`quakes`
Format

A data frame with 1000 observations on 5 variables.

[,1] lat numeric Latitude of event
[,2] long numeric Longitude
[,3] depth numeric Depth (km)
[,4] mag numeric Richter Magnitude
[,5] stations numeric Number of stations reporting

Details

There are two clear planes of seismic activity. One is a major plate junction; the other is the Tonga trench off New Zealand. These data constitute a subsample from a larger dataset of containing 5000 observations.

Source

This is one of the Harvard PRIM-H project data sets. They in turn obtained it from Dr. John Woodhouse, Dept. of Geophysics, Harvard University.

Examples

require(graphics)
pairs(quakes, main = "Fiji Earthquakes, N = 1000", cex.main = 1.2, pch = ".")

---

Random Numbers from Congruential Generator RANDU

Description

400 triples of successive random numbers were taken from the VAX FORTRAN function RANDU running under VMS 1.5.

Usage

randu

Format

A data frame with 400 observations on 3 variables named x, y and z which give the first, second and third random number in the triple.

Details

In three dimensional displays it is evident that the triples fall on 15 parallel planes in 3-space. This can be shown theoretically to be true for all triples from the RANDU generator.

These particular 400 triples start 5 apart in the sequence, that is they are ((U[5i+1], U[5i+2], U[5i+3]), i= 0, . . . , 399), and they are rounded to 6 decimal places.

Under VMS versions 2.0 and higher, this problem has been fixed.
rivers

Source

David Donoho

Examples

```r
## We could re-generate the dataset by the following R code
seed <- as.double(1)
RANDU <- function() {
  seed <<- ((2^16 + 3) * seed) %% (2^31)
  seed/(2^31)
}
for(i in 1:400) {
  U <- c(RANDU(), RANDU(), RANDU(), RANDU(), RANDU())
  print(round(U[1:3], 6))
}
```

rivers

<table>
<thead>
<tr>
<th>Lengths of Major North American Rivers</th>
</tr>
</thead>
</table>

Description

This data set gives the lengths (in miles) of 141 “major” rivers in North America, as compiled by the US Geological Survey.

Usage

rivers

Format

A vector containing 141 observations.

Source

References

Measurements on Petroleum Rock Samples

Description

Measurements on 48 rock samples from a petroleum reservoir.

Usage

rock

Format

A data frame with 48 rows and 4 numeric columns.
Details

Twelve core samples from petroleum reservoirs were sampled by 4 cross-sections. Each core sample was measured for permeability, and each cross-section has total area of pores, total perimeter of pores, and shape.

Source

Data from BP Research, image analysis by Ronit Katz, U. Oxford.

sleep

Student’s Sleep Data

Description

Data which show the effect of two soporific drugs (increase in hours of sleep compared to control) on 10 patients.

Usage

sleep

Format

A data frame with 20 observations on 3 variables.

[, 1] extra numeric increase in hours of sleep
[, 2] group factor drug given
[, 3] ID factor patient ID

Details

The group variable name may be misleading about the data: They represent measurements on 10 persons, not in groups.

Source

Student (1908) The probable error of the mean. Biometrika, 6, 20.

References

Examples

```r
require(stats)
## Student's paired t-test
with(sleep,
  t.test(extra[group == 1],
         extra[group == 2], paired = TRUE))

## The sleep *prolongations*
sleep1 <- with(sleep, extra[group == 2] - extra[group == 1])
summary(sleep1)
stripchart(sleep1, method = "stack", xlab = "hours",
          main = "Sleep prolongation (n = 10)"
)  
boxplot(sleep1, horizontal = TRUE, add = TRUE,
        at = .6, pars = list(boxwex = 0.5, staplewex = 0.25))
```

stackloss

### Brownlee's Stack Loss Plant Data

Description

Operational data of a plant for the oxidation of ammonia to nitric acid.

Usage

```r
stackloss
stack.x
stack.loss
```

Format

stackloss is a data frame with 21 observations on 4 variables.

```
[,1]  Air Flow  Flow of cooling air
[.2]  Water Temp  Cooling Water Inlet Temperature
[.3] Acid Conc.  Concentration of acid [per 1000, minus 500]
[.4] stack.loss  Stack loss
```

For compatibility with S-PLUS, the data sets `stack.x`, a matrix with the first three (independent) variables of the data frame, and `stack.loss`, the numeric vector giving the fourth (dependent) variable, are provided as well.

Details

“Obtained from 21 days of operation of a plant for the oxidation of ammonia (NH₃) to nitric acid (HNO₃). The nitric oxides produced are absorbed in a countercurrent absorption tower”. (Brownlee, cited by Dodge, slightly reformatted by MM.)

**Air Flow** represents the rate of operation of the plant. **Water Temp** is the temperature of cooling water circulated through coils in the absorption tower. **Acid Conc.** is the concentration of the acid circulating, minus 50, times 10: that is, 89 corresponds to 58.9 per cent acid. **stack.loss** (the
dependent variable) is 10 times the percentage of the ingoing ammonia to the plant that escapes from the absorption column unabsorbed; that is, an (inverse) measure of the over-all efficiency of the plant.

Source

References

Examples

```r
require(stats)
summary(lm.stack <- lm(stack.loss ~ stack.x))
```

---

### state

**US State Facts and Figures**

**Description**

Data sets related to the 50 states of the United States of America.

**Usage**

- `state.abb`
- `state.area`
- `state.center`
- `state.division`
- `state.name`
- `state.region`
- `state.x77`

**Details**

R currently contains the following “state” data sets. Note that all data are arranged according to alphabetical order of the state names.

- `state.abb`: character vector of 2-letter abbreviations for the state names.
- `state.area`: numeric vector of state areas (in square miles).
- `state.center`: list with components named `x` and `y` giving the approximate geographic center of each state in negative longitude and latitude. Alaska and Hawaii are placed just off the West Coast.
- `state.division`: factor giving state divisions (New England, Middle Atlantic, South Atlantic, East South Central, West South Central, East North Central, West North Central, Mountain, and Pacific).
state.name: character vector giving the full state names.
state.region: factor giving the region (Northeast, South, North Central, West) that each state belongs to.
state.x77: matrix with 50 rows and 8 columns giving the following statistics in the respective columns.
  Population: population estimate as of July 1, 1975
  Income: per capita income (1974)
  Illiteracy: illiteracy (1970, percent of population)
  Life Exp: life expectancy in years (1969–71)
  Murder: murder and non-negligent manslaughter rate per 100,000 population (1976)
  HS Grad: percent high-school graduates (1970)
  Frost: mean number of days with minimum temperature below freezing (1931–1960) in capital or large city
  Area: land area in square miles

sunspot.year

See Also

sunspot.month is a longer version of sunspots: the latter runs until 1983 and is kept fixed (for reproducibility as example dataset).

Examples

```r
require(stats); require(graphics)
## Compare the monthly series
plot(sunspot.month,
     main="sunspot.month & sunspots [package'datasets']", col=2)
lines(sunspots) # -> faint differences where they overlap

## Now look at the difference :
all(tsp(sunspots) [c(1,3)] == tsp(sunspot.month)[c(1,3)]) ## Start & Periodicity are the same
n1 <- length(sunspots)
table(eq <- sunspots == sunspot.month[1:n1]) #> 132 are different !
i <- which(!eq)
rug(time(eq)[i])
s1 <- sunspots[i] ; s2 <- sunspot.month[i]
cbind(i = i, time = time(sunspots)[i], sunspots = s1, ss.month = s2,
      perc.diff = round(100*2*abs(s1-s2)/(s1+s2), 1))

## How to recreate the "old" sunspot.month (R <= 3.0.3):
.sunspot.diff <- cbind(
i = c(1202L, 1256L, 1258L, 1301L, 1407L, 1429L, 1452L, 1455L, 
    1663L, 2151L, 2329L, 2498L, 2594L, 2694L, 2819L),
    res10 = c(1L, 1L, 1L, -1L, -1L, -1L, 1L, -1L, 
      1L, 1L, 1L, 1L, 1L, 20L, 1L))
ssm0 <- sunspot.month[1:2988]
with(as.data.frame(.sunspot.diff), ssm0[i] <<- ssm0[i] - res10/10)
sunspot.month.0 <- ts(ssm0, start = 1749, frequency = 12)
```

sunspot.year

Yearly Sunspot Data, 1700–1988

Description

Yearly numbers of sunspots from 1700 to 1988 (rounded to one digit).

Note that monthly numbers are available as sunspot.month, though starting slightly later.

Usage

sunspot.year

Format

The univariate time series sunspot.year contains 289 observations, and is of class "ts".

Source

See Also

For monthly sunspot numbers, see `sunspot.month` and `sunspots`.

Regularly updated yearly sunspot numbers are available from WDC-SILSO, Royal Observatory of Belgium, at `http://www.sidc.be/silso/datafiles`

Examples

```r
utils::str(sm <- sunspots)  # the monthly version we keep unchanged
utils::str(sy <- sunspot.year)
## The common time interval
(t1 <- c(max(start(sm), start(sy)), 1))  # Jan 1749
(t2 <- c(min(end(sm)[1], end(sy)[1]), 12))  # Dec 1983
s.m <- window(sm, start=t1, end=t2)
s.y <- window(sy, start=t1, end=t2[1])  # (irrelevant warning)
stopifnot(length(s.y) * 12 == length(s.m),
  ## The yearly series *is* close to the averages of the monthly one:
  all.equal(s.y, aggregate(s.m, FUN = mean), tol = 0.0020))
## NOTE: Strangely, correctly weighting the number of days per month
## (using 28.25 for February) is *not* closer than the simple mean:
## ndays <- c(31, 28.25, rep(c(31,30, 31,30, 31), 2))
all.equal(s.y, aggregate(s.m, FUN = mean))  # 0.0013
all.equal(s.y, aggregate(s.m, FUN = weighted.mean, w = ndays))  # 0.0017
```

Description

Annual mean relative sunspot numbers from 1749 to 1983. Collected at Swiss Federal Observatory, Zurich until 1960, then Tokyo Astronomical Observatory.

Usage

`sunspots`

Format

A time series of monthly data from 1749 to 1983.

Source

See Also

`sunspot.month` has a longer (and a bit different) series, `sunspot.year` is a much shorter one. See there for getting more current sunspot numbers.

Examples

```r
require(graphics)
plot(sunspots, main = "sunspots data", xlab = "Year",
     ylab = "Monthly sunspot numbers")
```
Description

Standardized fertility measure and socio-economic indicators for each of 47 French-speaking provinces of Switzerland at about 1888.

Usage

swiss

Format

A data frame with 47 observations on 6 variables, each of which is in percent, i.e., in $[0, 100]$.

\[
\begin{array}{ll}
[.1] & \text{Fertility} \quad I_p, \text{‘common standardized fertility measure’} \\
[.2] & \text{Agriculture} \quad \% \text{ of males involved in agriculture as occupation} \\
[.3] & \text{Examination} \quad \% \text{ draftees receiving highest mark on army examination} \\
[.4] & \text{Education} \quad \% \text{ education beyond primary school for draftees.} \\
[.5] & \text{Catholic} \quad \% \text{ ‘catholic’ (as opposed to ‘protestant’).} \\
[.6] & \text{Infant.Mortality} \quad \text{live births who live less than 1 year.}
\end{array}
\]

All variables but ‘Fertility’ give proportions of the population.

Details

(paraphrasing Mosteller and Tukey):

Switzerland, in 1888, was entering a period known as the demographic transition; i.e., its fertility was beginning to fall from the high level typical of underdeveloped countries.

The data collected are for 47 French-speaking “provinces” at about 1888.

Here, all variables are scaled to $[0, 100]$, where in the original, all but “Catholic” were scaled to $[0, 1]$.

Note

Files for all 182 districts in 1888 and other years have been available at https://opr.princeton.edu/archive/pefp/switz.aspx.

They state that variables Examination and Education are averages for 1887, 1888 and 1889.

Source

Project “16P5”, pages 549–551 in

References

Examples

```r
require(stats); require(graphics)
pairs(swiss, panel = panel.smooth, main = "swiss data", 
     col = 3 + (swiss$Catholic > 50))
summary(lm(Fertility ~ . , data = swiss))
```

---

**Theoph**  
*Pharmacokinetics of Theophylline*

Description

The Theoph data frame has 132 rows and 5 columns of data from an experiment on the pharmacokinetics of theophylline.

Usage

Theoph

Format

An object of class c("nfnGroupedData","nfGroupedData","groupedData","data.frame") containing the following columns:

- **Subject**: an ordered factor with levels 1, ..., 12 identifying the subject on whom the observation was made. The ordering is by increasing maximum concentration of theophylline observed.
- **Wt**: weight of the subject (kg).
- **Dose**: dose of theophylline administered orally to the subject (mg/kg).
- **Time**: time since drug administration when the sample was drawn (hr).
- **conc**: theophylline concentration in the sample (mg/L).

Details

Boeckmann, Sheiner and Beal (1994) report data from a study by Dr. Robert Upton of the kinetics of the anti-asthmatic drug theophylline. Twelve subjects were given oral doses of theophylline then serum concentrations were measured at 11 time points over the next 25 hours.

These data are analyzed in Davidian and Giltinan (1995) and Pinheiro and Bates (2000) using a two-compartment open pharmacokinetic model, for which a self-starting model function, SSfol, is available.

This dataset was originally part of package nlme, and that has methods (including for [, as.data.frame, plot and print) for its grouped-data classes.
Source

See Also

SSfol

Examples

```r
require(stats); require(graphics)

coplot(conc ~ Time | Subject, data = Theoph, show.given = FALSE)
Theoph.4 <- subset(Theoph, Subject == 4)
fm1 <- nls(conc ~ SSfol(Dose, Time, lKe, lKa, lCl),
data = Theoph.4)
summary(fm1)
plot(conc ~ Time, data = Theoph.4,
xlab = "Time since drug administration (hr)",
ylab = "Theophylline concentration (mg/L)",
main = "Observed concentrations and fitted model",
sub = "Theophylline data - Subject 4 only",
las = 1, col = 4)
xvals <- seq(0, par("usr")[2], length.out = 55)
lines(xvals, predict(fm1, newdata = list(Time = xvals)),
col = 4)
```

Titanic

Survival of passengers on the Titanic

Description

This data set provides information on the fate of passengers on the fatal maiden voyage of the ocean liner ‘Titanic’, summarized according to economic status (class), sex, age and survival.

Usage

Titanic

Format

A 4-dimensional array resulting from cross-tabulating 2201 observations on 4 variables. The variables and their levels are as follows:

<table>
<thead>
<tr>
<th>No</th>
<th>Name</th>
<th>Levels</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Class</td>
<td>1st, 2nd, 3rd, Crew</td>
</tr>
<tr>
<td>2</td>
<td>Sex</td>
<td>Male, Female</td>
</tr>
<tr>
<td>3</td>
<td>Age</td>
<td>Child, Adult</td>
</tr>
<tr>
<td>4</td>
<td>Survived</td>
<td>No, Yes</td>
</tr>
</tbody>
</table>
Details

The sinking of the Titanic is a famous event, and new books are still being published about it. Many well-known facts—from the proportions of first-class passengers to the ‘women and children first’ policy, and the fact that that policy was not entirely successful in saving the women and children in the third class—are reflected in the survival rates for various classes of passenger.

These data were originally collected by the British Board of Trade in their investigation of the sinking. Note that there is not complete agreement among primary sources as to the exact numbers on board, rescued, or lost.

Due in particular to the very successful film ‘Titanic’, the last years saw a rise in public interest in the Titanic. Very detailed data about the passengers is now available on the Internet, at sites such as Encyclopedia Titanica (https://www.encyclopedia-titanica.org/).

Source

The source provides a data set recording class, sex, age, and survival status for each person on board of the Titanic, and is based on data originally collected by the British Board of Trade and reprinted in:

Examples

```r
require(graphics)
mosaicplot(Titanic, main = "Survival on the Titanic")
## Higher survival rates in children?
apply(Titanic, c(3, 4), sum)
## Higher survival rates in females?
apply(Titanic, c(2, 4), sum)
## Use loglm() in package 'MASS' for further analysis ...
```

ToothGrowth

*The Effect of Vitamin C on Tooth Growth in Guinea Pigs*

Description

The response is the length of odontoblasts (cells responsible for tooth growth) in 60 guinea pigs. Each animal received one of three dose levels of vitamin C (0.5, 1, and 2 mg/day) by one of two delivery methods, orange juice or ascorbic acid (a form of vitamin C and coded as VC).

Usage

ToothGrowth

Format

A data frame with 60 observations on 3 variables.

```
[1,] len   numeric Tooth length
[2,] supp  factor Supplement type (VC or OJ).
[3,] dose  numeric Dose in milligrams/day
```
Source

References

Examples

```r
require(graphics)
coplot(len ~ dose | supp, data = ToothGrowth, panel = panel.smooth,
       xlab = "ToothGrowth data: length vs dose, given type of supplement")
```

<table>
<thead>
<tr>
<th>treering</th>
</tr>
</thead>
<tbody>
<tr>
<td><em>Yearly Treering Data, -6000–1979</em></td>
</tr>
</tbody>
</table>

Description

Contains normalized tree-ring widths in dimensionless units.

Usage

treering

Format

A univariate time series with 7981 observations. The object is of class "ts".

Each tree ring corresponds to one year.

Details

The data were recorded by Donald A. Graybill, 1980, from Gt Basin Bristlecone Pine 2805M, 3726-11810 in Methuselah Walk, California.

Source

Time Series Data Library: [https://robjhyndman.com/TSDL/](https://robjhyndman.com/TSDL/), series ‘CA535.DAT’

trees

Diameter, Height and Volume for Black Cherry Trees

Description
This data set provides measurements of the diameter, height and volume of timber in 31 felled black cherry trees. Note that the diameter (in inches) is erroneously labelled Girth in the data. It is measured at 4 ft 6 in above the ground.

Usage
trees

Format
A data frame with 31 observations on 3 variables.

[,1] Girth numeric Tree diameter (rather than girth, actually) in inches
[,2] Height numeric Height in ft
[,3] Volume numeric Volume of timber in cubic ft

Source

References

Examples
require(stats); require(graphics)
pairs(trees, panel = panel.smooth, main = "trees data")
plot(Volume ~ Girth, data = trees, log = "xy")
coplot(log(Volume) ~ log(Girth) | Height, data = trees,
panel = panel.smooth)
summary(fm1 <- lm(log(Volume) ~ log(Girth), data = trees))
summary(fm2 <- update(fm1, ~ . + log(Height), data = trees))
step(fm2)
## i.e., Volume ~= c * Height * Girth^2 seems reasonable

UCBAAdmissions
Student Admissions at UC Berkeley

Description
Aggregate data on applicants to graduate school at Berkeley for the six largest departments in 1973 classified by admission and sex.
Usage

UCBAdmissions

Format

A 3-dimensional array resulting from cross-tabulating 4526 observations on 3 variables. The variables and their levels are as follows:

<table>
<thead>
<tr>
<th>No</th>
<th>Name</th>
<th>Levels</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Admit</td>
<td>Admitted, Rejected</td>
</tr>
<tr>
<td>2</td>
<td>Gender</td>
<td>Male, Female</td>
</tr>
<tr>
<td>3</td>
<td>Dept</td>
<td>A, B, C, D, E, F</td>
</tr>
</tbody>
</table>

Details

This data set is frequently used for illustrating Simpson’s paradox, see Bickel et al (1975). At issue is whether the data show evidence of sex bias in admission practices. There were 2691 male applicants, of whom 1198 (44.5%) were admitted, compared with 1835 female applicants of whom 557 (30.4%) were admitted. This gives a sample odds ratio of 1.83, indicating that males were almost twice as likely to be admitted. In fact, graphical methods (as in the example below) or log-linear modelling show that the apparent association between admission and sex stems from differences in the tendency of males and females to apply to the individual departments (females used to apply more to departments with higher rejection rates).

This data set can also be used for illustrating methods for graphical display of categorical data, such as the general-purpose mosaicplot or the fourfoldplot for 2-by-2-by-\(k\) tables.

References

Examples

require(graphics)

X[, 1] <- log10(X[, 1]) - 4
arima(log10(Seatbelts[, "drivers"]), c(1, 0, 0),
  seasonal = list(order = c(1, 0, 0)), xreg = X)

UKgas

UK Quarterly Gas Consumption

Description
Quarterly UK gas consumption from 1960Q1 to 1986Q4, in millions of therms.

Usage
UKgas

Format
A quarterly time series of length 108.

Source

Examples
## maybe str(UKgas) ; plot(UKgas) ...

UKLungDeaths

Monthly Deaths from Lung Diseases in the UK

Description
Three time series giving the monthly deaths from bronchitis, emphysema and asthma in the UK, 1974–1979, both sexes (ldeaths), males (mdeaths) and females (fdeaths).

Usage
ldeaths
fdeaths
mdeaths

Source
Examples

```r
require(stats); require(graphics) # for time
plot(ldeaths)
plot(mdeaths, fdeaths)
## Better labels:
yr <- floor(tt <- time(mdeaths))
plot(mdeaths, fdeaths,
    xy.labels = paste(month.abb[12*(tt - yr)], yr-1900, sep = " "))
```

USAccDeaths

**Accidental Deaths in the US 1973–1978**

Description

A time series giving the monthly totals of accidental deaths in the USA. The values for the first six months of 1979 are 7798 7406 8363 8460 9217 9316.

Usage

USAccDeaths

Source

USArrests

**Violent Crime Rates by US State**

Description

This data set contains statistics, in arrests per 100,000 residents for assault, murder, and rape in each of the 50 US states in 1973. Also given is the percent of the population living in urban areas.

Usage

USArrests

Format

A data frame with 50 observations on 4 variables.

<table>
<thead>
<tr>
<th></th>
<th>Murder</th>
<th>Assault</th>
<th>UrbanPop</th>
<th>Rape</th>
</tr>
</thead>
<tbody>
<tr>
<td>.1</td>
<td>numeric</td>
<td>numeric</td>
<td>numeric</td>
<td>numeric</td>
</tr>
<tr>
<td>.2</td>
<td>Murder arrests (per 100,000)</td>
<td>Assault arrests (per 100,000)</td>
<td>Percent urban population</td>
<td>Rape arrests (per 100,000)</td>
</tr>
</tbody>
</table>

Note

USArrests contains the data as in McNeil’s monograph. For the UrbanPop percentages, a review of the table (No. 21) in the Statistical Abstracts 1975 reveals a transcription error for Maryland.
(and that McNeil used the same “round to even” rule that R’s `round()` uses), as found by Daniel S Coven (Arizona).
See the example below on how to correct the error and improve accuracy for the ‘<n>.5’ percentages.

### Source

### References

### See Also
The `state` data sets.

### Examples
```r
summary(USArrests)
require(graphics)
pairs(USArrests, panel = panel.smooth, main = "USArrests data")
```

```r
## Difference between 'USArrests' and its correction
USArrests["Maryland", "UrbanPop"] # 67 -- the transcription error
UA.C <- USArrests
UA.C["Maryland", "UrbanPop"] <- 76.6

## also +/- 0.5 to restore the original <n>.5 percentages
s5u <- c("Colorado", "Florida", "Mississippi", "Wyoming")
s5d <- c("Nebraska", "Pennsylvania")
UA.C[s5u, "UrbanPop"] <- UA.C[s5u, "UrbanPop"] + 0.5
UA.C[s5d, "UrbanPop"] <- UA.C[s5d, "UrbanPop"] - 0.5
## ==> UA.C is now a *C*orrected version of USArrests
```

### Description
Lawyers’ ratings of state judges in the US Superior Court.

### Usage
`USJudgeRatings`

### Format
A data frame containing 43 observations on 12 numeric variables.
[.1] CONT Number of contacts of lawyer with judge.
[.2] INTG Judicial integrity.
[.3] DMNR Demeanor.
[.5] CFMG Case flow managing.
[.6] DECI Prompt decisions.
[.7] PREP Preparation for trial.
[.8] FAMI Familiarity with law.
[.9] ORAL Sound oral rulings.
[.10] WRIT Sound written rulings.
[.11] PHYS Physical ability.
[.12] RTEN Worthy of retention.

Source

medpolish(log10(USPersonalExpenditure))
**uspop**

*Populations Recorded by the US Census*

**Description**

This data set gives the population of the United States (in millions) as recorded by the decennial census for the period 1790–1970.

**Usage**

uspop

**Format**

A time series of 19 values.

**Source**

**Examples**

```r
require(graphics)
plot(uspop, log = "y", main = "uspop data", xlab = "Year",
     ylab = "U.S. Population (millions)")
```

---

**VADeaths**

*Death Rates in Virginia (1940)*

**Description**

Death rates per 1000 in Virginia in 1940.

**Usage**

VADeaths

**Format**

A matrix with 5 rows and 4 columns.

**Details**

The death rates are measured per 1000 population per year. They are cross-classified by age group (rows) and population group (columns). The age groups are: 50–54, 55–59, 60–64, 65–69, 70–74 and the population groups are Rural/Male, Rural/Female, Urban/Male and Urban/Female.

This provides a rather nice 3-way analysis of variance example.
Source

References

Examples

```r
require(stats); require(graphics)

### volcano

*Topographic Information on Auckland’s Maunga Whau Volcano*

**Description**

Maunga Whau (Mt Eden) is one of about 50 volcanos in the Auckland volcanic field. This data set gives topographic information for Maunga Whau on a 10m by 10m grid.

**Usage**

```r
volcano
```

**Format**

A matrix with 87 rows and 61 columns, rows corresponding to grid lines running east to west and columns to grid lines running south to north.

**Source**

Digitized from a topographic map by Ross Ihaka. These data should not be regarded as accurate.

**See Also**

`filled.contour` for a nice plot.
The Number of Breaks in Yarn during Weaving

Description
This data set gives the number of warp breaks per loom, where a loom corresponds to a fixed length of yarn.

Usage
warpbreaks

Format
A data frame with 54 observations on 3 variables.

[,1] breaks numeric The number of breaks
[,2] wool factor The type of wool (A or B)
[,3] tension factor The level of tension (L, M, H)

There are measurements on 9 looms for each of the six types of warp (AL, AM, AH, BL, BM, BH).

Source

References

See Also
xtabs for ways to display these data as a table.

Examples
require(stats); require(graphics)
summary(warpbreaks)
opar <- par(mfrow = c(1, 2), oma = c(0, 0, 1.1, 0))
plot(breaks ~ tension, data = warpbreaks, col = "lightgray",
     varwidth = TRUE, subset = wool == "A", main = "Wool A")
plot(breaks ~ tension, data = warpbreaks, col = "lightgray",
     varwidth = TRUE, subset = wool == "B", main = "Wool B")
mtext("warpbreaks data", side = 3, outer = TRUE)
par(opar)
summary(fm1 <- lm(breaks ~ wool*tension, data = warpbreaks))
**women**

*Average Heights and Weights for American Women*

**Description**
This data set gives the average heights and weights for American women aged 30–39.

**Usage**

women

**Format**
A data frame with 15 observations on 2 variables.

<table>
<thead>
<tr>
<th>[,1]</th>
<th>height</th>
<th>numeric</th>
<th>Height (in)</th>
</tr>
</thead>
<tbody>
<tr>
<td>[,2]</td>
<td>weight</td>
<td>numeric</td>
<td>Weight (lbs)</td>
</tr>
</tbody>
</table>

**Details**
The data set appears to have been taken from the American Society of Actuaries *Build and Blood Pressure Study* for some (unknown to us) earlier year.

The World Almanac notes: “The figures represent weights in ordinary indoor clothing and shoes, and heights with shoes”.

**Source**

**References**

**Examples**

```r
require(graphics)
plot(women, xlab = "Height (in)", ylab = "Weight (lb)",
     main = "women data: American women aged 30-39")
```

---

**WorldPhones**

*The World’s Telephones*

**Description**
The number of telephones in various regions of the world (in thousands).

**Usage**

WorldPhones
WWWusage

Format

A matrix with 7 rows and 8 columns. The columns of the matrix give the figures for a given region, and the rows the figures for a year.

The regions are: North America, Europe, Asia, South America, Oceania, Africa, Central America.

Source

References

Examples

```r
require(graphics)
matplot(rownames(WorldPhones), WorldPhones, type = "b", log = "y",
       xlab = "Year", ylab = "Number of telephones (1000's)"
       legend(1951.5, 80000, colnames(WorldPhones), col = 1:6, lty = 1:5,
              pch = rep(21, 7))
title(main = "World phones data: log scale for response")
```

Chapter 4
The grDevices package

grDevices-package  The R Graphics Devices and Support for Colours and Fonts

Description
Graphics devices and support for base and grid graphics

Details
This package contains functions which support both base and grid graphics.
For a complete list of functions, use library(help = "grDevices").

Author(s)
R Core Team and contributors worldwide
Maintainer: R Core Team <R-core@r-project.org>

adjustcolor  Adjust Colors in One or More Directions Conveniently.

Description
Adjust or modify a vector of colors by “turning knobs” on one or more coordinates in \((r, g, b, \alpha)\) space, typically by up or down scaling them.

Usage
adjustcolor(col, alpha.f = 1, red.f = 1, green.f = 1, blue.f = 1,
offset = c(0, 0, 0, 0),
transform = diag(c(red.f, green.f, blue.f, alpha.f)))

731
Arguments

- **col**: vector of colors, in any format that `col2rgb()` accepts
- **alpha.f**: factor modifying the opacity alpha; typically in \([0,1]\)
- **red.f, green.f, blue.f**: factors modifying the "red-", "green-" or "blue-"ness of the colors, respectively.
- **offset, transform**

Value

a color vector of the same length as `col`, effectively the result of `rgb()`.

See Also

`rgb, col2rgb`. For more sophisticated color constructions: `convertColor`

Examples

```r
## Illustrative examples:
opal <- palette("default")
stopifnot(identical(adjustcolor(1:8, 0.75),
                      adjustcolor(palette(), 0.75)))
cbind(palette(), adjustcolor(1:8, 0.75))

## alpha = 1/2 * previous alpha --> opaque colors
x <- palette(adjustcolor(palette(), 0.5))
sines <- outer(1:20, 1:4, function(x, y) sin(x / 20 * pi * y))
matplot(sines, type = "b", pch = 21:23, col = 2:5, bg = 2:5,
        main = "Using an 'opaque ('translucent') color palette")

x. <- adjustcolor(x, offset = c(0.5, 0.5, 0.5, 0), # <- "more white"
                  transform = diag(c(.7, .7, .7, 0.6)))
cbind(x, x.)

op <- par(bg = adjustcolor("goldenrod", offset = -rep(.4, 4)), xpd = NA)
plot(0:9, 0:9, type = "n", axes = FALSE, xlab = "", ylab = "",
     main = "adjustcolor() -> translucent")
text(1:8, labels = paste0(x,"++"), col = x., cex = 8)
par(op)

## and

(M <- cbind( rbind( matrix(1/3, 3, 3), 0), c(0, 0, 0, 1))))
adjustcolor(x, transform = M)

## revert to previous palette: active
palette(opal)
```
as.graphicsAnnot  Coerce an Object for Graphics Annotation

Description

Coerce an R object into a form suitable for graphics annotation.

Usage

as.graphicsAnnot(x)

Arguments

x  an R object

Details

Expressions, calls and names (as used by plotmath) are passed through unchanged. All other objects with an explicit class (as determined by is.object) are coerced by as.character to character vectors.

All the graphics and grid functions which use this coerce calls and names to expressions internally.

Value

A language object or a character vector.

as.raster  Create a Raster Object

Description

Functions to create a raster object (representing a bitmap image) and coerce other objects to a raster object.

Usage

is.raster(x)
as.raster(x, ...)

## S3 method for class 'matrix'
as.raster(x, max = 1, ...)
## S3 method for class 'array'
as.raster(x, max = 1, ...)

## S3 method for class 'logical'
as.raster(x, max = 1, ...)
## S3 method for class 'numeric'
as.raster(x, max = 1, ...)
## S3 method for class 'character'
as.raster(x, max = 1, ...)
## S3 method for class 'raw'
as.raster(x, max = 255L, ...)
Arguments

- `x` any R object.
- `max` number giving the maximum of the color values range.
- `...` further arguments passed to or from other methods.

Details

An object of class "raster" is a matrix of colour values as given by `rgb` representing a bitmap image.

It is not expected that the user will need to call these functions directly; functions to render bitmap images in graphics packages will make use of the `as.raster()` function to generate a raster object from their input.

The `as.raster()` function is (S3) generic so methods can be written to convert other R objects to a raster object.

The default implementation for numeric matrices interprets scalar values on black-to-white scale.

Raster objects can be subsetted like a matrix and it is possible to assign to a subset of a raster object.

There is a method for converting a raster object to a `matrix` (of colour strings).

Raster objects can be compared for equality or inequality (with each other or with a colour string).

There is a `is.na` method which returns a logical matrix of the same dimensions as the raster object.

Note that NA values are interpreted as the fully transparent colour by some (but not all) graphics devices.

Value

For `as.raster()`, a raster object.

For `is.raster()`, a logical indicating whether `x` is a raster object.

Note

Raster images are internally represented row-first, which can cause confusion when trying to manipulate a raster object. The recommended approach is to coerce a raster to a matrix, perform the manipulation, then convert back to a raster.

Examples

```r
# A red gradient
as.raster(matrix(hcl(0, 80, seq(50, 80, 10)),
nrow = 4, ncol = 5))

# Vectors are 1-column matrices ...
# character vectors are color names ...
as.raster(hcl(0, 80, seq(50, 80, 10)))
# numeric vectors are greyscale ...
as.raster(1:5, max = 5)
# logical vectors are black and white ...
as.raster(1:10 %% 2 == 0)

# ... unless nrow/ncol are supplied ...
as.raster(1:10 %% 2 == 0, nrow = 1)

# Matrix can also be logical or numeric (or raw) ...
```
axisTicks

Compute Pretty Axis Tick Scales

Description
Compute pretty axis scales and tick mark locations, the same way as traditional R graphics do it. This is interesting particularly for log scale axes.

Usage
axisTicks(usr, log, axp = NULL, nint = 5)
.axisPars(usr, log = FALSE, nintLog = 5)

Arguments
usr numeric vector of length 2, with \(c(\text{min}, \text{max})\) axis extents.
log logical indicating if a log scale is (thought to be) in use.
axp numeric vector of length 3, \(c(\text{mi}, \text{ma}, \text{n.})\), with identical meaning to
par("?axp") (where ? is x or y), namely “pretty” axis extents, and an integer
code n..
nint, nintLog positive integer value indicating (approximately) the desired number of intervals. nintLog is used only for the case log = TRUE.

Details
axisTicks(usr,*) calls .axisPars(usr,..) to set axp when that is missing or NULL.
Apart from that, axisTicks() just calls the C function CreateAtVector() in
"<Rsrc>/src/main/plot.c" which is also called by the base graphics package function
axis(side,*) when its argument at is not specified.
Since R 4.1.0, the underlying C CreateAtVector() has been tuned to provide a considerably more balanced (symmetric) set of tick locations.
Value

axisTicks() returns a numeric vector of potential axis tick locations, of length approximately
nint + 1.
.axisPars() returns a list with components

axp    numeric vector of length 2, c(min., max.), of pretty axis extents.

n    integer (code), with the same meaning as par("?axp")[3].

See Also

axTicks, axis, and par all from the graphics package.

Examples

##--- Demonstrating correspondence between graphics' axis() and the graphics-engine agnostic  axisTicks() :
require("graphics")
plot(10*(0:10)); (pu <- par("usr"))
aX <- function(side, at, ...)
  axis(side, at = at, labels = FALSE, lwd.ticks = 2, col.ticks = 2,
       tck = 0.05, ...)
aX(1, print(xa <- axisTicks(pu[1:2], log = FALSE)))  # x axis
aX(2, print(ya <- axisTicks(pu[3:4], log = FALSE)))  # y axis
axisTicks(pu[3:4], log = FALSE, n = 10)
plot(10*(0:10), log = "y"); (pu <- par("usr"))
daX(2, print(ya <- axisTicks(pu[3:4], log = TRUE)))  # y axis
plot(2^10:0:9, log = "y"); (pu <- par("usr"))
daX(2, print(ya <- axisTicks(pu[3:4], log = TRUE)))  # y axis

---

boxplot.stats  Box Plot Statistics

Description

This function is typically called by another function to gather the statistics necessary for producing
box plots, but may be invoked separately.

Usage

boxplot.stats(x, coef = 1.5, do.conf = TRUE, do.out = TRUE)

Arguments

x    a numeric vector for which the boxplot will be constructed (NAs and NaNs are
      allowed and omitted).
this determines how far the plot ‘whiskers’ extend out from the box. If coef is positive, the whiskers extend to the most extreme data point which is no more than coef times the length of the box away from the box. A value of zero causes the whiskers to extend to the data extremes (and no outliers be returned).

do.conf, do.out

logicals; if FALSE, the conf or out component respectively will be empty in the result.

Details

The two ‘hinges’ are versions of the first and third quartile, i.e., close to quantile(x,c(1, 3)/4). The hinges equal the quartiles for odd \( n \) (where \( n \equiv \text{length}(x) \)) and differ for even \( n \). Whereas the quartiles only equal observations for \( n \equiv 4 \equiv 1 \mod 4 \), the hinges do so additionally for \( n \equiv 2 \mod 4 \), and are in the middle of two observations otherwise.

The notches (if requested) extend to \(+/-1.58 \text{IQR}/\sqrt{n}\). This seems to be based on the same calculations as the formula with 1.57 in Chambers et al (1983, p. 62), given in McGill et al (1978, p. 16). They are based on asymptotic normality of the median and roughly equal sample sizes for the two medians being compared, and are said to be rather insensitive to the underlying distributions of the samples. The idea appears to be to give roughly a 95% confidence interval for the difference in two medians.

Value

List with named components as follows:

- stats: a vector of length 5, containing the extreme of the lower whisker, the lower ‘hinge’, the median, the upper ‘hinge’ and the extreme of the upper whisker.
- n: the number of non-NA observations in the sample.
- conf: the lower and upper extremes of the ‘notch’ (if(do.conf)). See the details.
- out: the values of any data points which lie beyond the extremes of the whiskers (if(do.out)).

Note that $stats and $conf are sorted in increasing order, unlike S, and that $n and $out include any \(+/-\text{Inf}\) values.

References

See Also

- fivenum, boxplot, bxp.
Examples

```r
require(stats)
x <- c(1:100, 1000)
(b1 <- boxplot.stats(x))
(b2 <- boxplot.stats(x, do.conf = FALSE, do.out = FALSE))
stopifnot(b1 $ stats == b2 $ stats) # do.out = FALSE is still robust
boxplot.stats(x, coef = 3, do.conf = FALSE)
## no outlier treatment:
boxplot.stats(x, coef = 0)

boxplot.stats(c(x, NA)) # slight change : n is 101
(r <- boxplot.stats(c(x, -1:1/0)))
stopifnot(r$out == c(1000, -Inf, Inf))
```

---

**bringToTop**

Assign Focus to a Window

**Description**

bringToTop brings the specified screen device’s window to the front of the window stack (and gives it focus). With first argument -1 it brings the console to the top. If `stay = TRUE`, the window is designated as a topmost window, i.e. it will stay on top of any regular window. `stay` may only be used when Rgui is run in SDI mode. This corresponds to the “Stay on top” popup menu item in Rgui.

**Usage**

```r
bringToTop(which = dev.cur(), stay = FALSE)
```

**Arguments**

- **which**: a device number, or -1.
- **stay**: whether to make the window stay on top.

**See Also**

`msgWindow`, `windows`
cairo

Cairographics-based SVG, PDF and PostScript Graphics Devices

Description

Graphics devices for SVG, PDF and PostScript graphics files using the cairo graphics API.

Usage

```r
svg(filename = if(onefile) "Rplots.svg" else "Rplot%03d.svg",
     width = 7, height = 7, pointsize = 12,
     onfile = FALSE, family = "sans", bg = "white",
     antialias = c("default", "none", "gray", "subpixel"),
     symbolfamily)
```

```r
cairo_pdf(filename = if(onefile) "Rplots.pdf" else "Rplot%03d.pdf",
          width = 7, height = 7, pointsize = 12,
          onfile = FALSE, family = "sans", bg = "white",
          antialias = c("default", "none", "gray", "subpixel"),
          fallback_resolution = 300, symbolfamily)
```

```r
cairo_ps(filename = if(onefile) "Rplots.ps" else "Rplot%03d.ps",
          width = 7, height = 7, pointsize = 12,
          onfile = FALSE, family = "sans", bg = "white",
          antialias = c("default", "none", "gray", "subpixel"),
          fallback_resolution = 300, symbolfamily)
```

Arguments

- `filename` the name of the output file. The page number is substituted if a C integer format is included in the character string, as in the default. (The result must be less than `PATH_MAX` characters long, and may be truncated if not. See `postscript` for further details.) Tilde expansion is performed where supported by the platform.
- `width` the width of the device in inches.
- `height` the height of the device in inches.
- `pointsize` the default pointsize of plotted text (in big points).
- `onfile` should all plots appear in one file or in separate files?
- `family` one of the device-independent font families, "sans", "serif" and "mono", or a character string specify a font family to be searched for in a system-dependent way.
  
  On unix-alikes (incl\ Mac), see the ‘Cairo fonts’ section in the help for `X11`.
- `bg` the initial background colour: can be overridden by setting `par("bg")`.
- `antialias` string, the type of anti-aliasing (if any) to be used; defaults to "default".
- `fallback_resolution` numeric: the resolution in dpi used when falling back to bitmap output. Prior to `R 3.3.0` this depended on the cairo implementation but was commonly 300.
- `symbolfamily` a length-one character string that specifies the font family to be used as the "symbol" font (e.g., for `plotmath` output).
**Details**

SVG (Scalar Vector Graphics) is a W3C standard for vector graphics. See [https://www.w3.org/Graphics/SVG/](https://www.w3.org/Graphics/SVG/). The output from `svg` is SVG version 1.1 for `onefile = FALSE` (the default), otherwise SVG 1.2. (Few SVG viewers are capable of displaying multi-page SVG files.)

Note that unlike `postscript` and `pdf`, `cairo_pdf` and `cairo_ps` sometimes record bitmaps and not vector graphics. On the other hand, they can (on suitable platforms) include a much wider range of UTF-8 glyphs, and embed the fonts used.

The output produced by `cairo_ps(onefile = FALSE)` will be encapsulated postscript on a platform with cairo >= 1.6.

R can be compiled without support for any of these devices: this will be reported if you attempt to use them on a system where they are not supported. They all require cairo version 1.2 (from 2006) or later.

If you plot more than one page on one of these devices and do not include something like `%d` for the sequence number in `file` (or set `onefile = TRUE`) the file will contain the last page plotted.

There is full support of semi-transparency, but using this is one of the things liable to trigger bitmap output (and will always do so for `cairo_ps`).

**Value**

A plot device is opened: nothing is returned to the R interpreter.

**Anti-aliasing**

Anti-aliasing is applied to both graphics and fonts. It is generally preferable for lines and text, but can lead to undesirable effects for fills, e.g. for `image` plots, and so is never used for fills.

`antialias = "default"` is in principle platform-dependent, but seems most often equivalent to `antialias = "gray"`.

**Conventions**

This section describes the implementation of the conventions for graphics devices set out in the `R Internals` manual.

- The default device size is in pixels (svg) or inches.
- Font sizes are in big points.
- The default font family is Helvetica.
- Line widths are multiples of 1/96 inch.
- Circle radii have a minimum of 1/72 inch.
- Colours are interpreted by the viewing application.

**Note**

Cairo 1.2.4 (seen in Centos/RHEL 5) is known to give incorrect SVG output.

In principle these devices are independent of X11 (as is seen by their presence on Windows). But on a Unix-alike the cairo libraries may be distributed as part of the X11 system and hence that (on macOS, XQuartz) may need to be installed.
cairoSymbolFont

Specify a Symbol Font

Description

Specify a symbol font for a Cairo-based graphics device. This function provides the opportunity to specify whether the font supports Private Use Area code points.

Usage

cairoSymbolFont(family, usePUA = TRUE)

Arguments

family A character vector giving the symbol font family name.
usePUA Does the font support Private Use Area code points?

Details

On Cairo-based graphics devices, when drawing with a symbol font (e.g., plotmath), Adobe Symbol Encoding characters are converted to UTF-8 code points. This conversion can use Private Use Area code points or not. It is useful to be able to specify this option because some fonts (e.g., the OpenSymbol font that is included in LibreOffice) have glyphs mapped to the Private Use Area and some fonts (e.g., Nimbus Sans L, the URW Fonts equivalent of Helvetica) do not.

Value

An object of class "CairoSymbolFont".

See Also

cairo_pdf.

Examples

## Not run:
## If a font uses PUA, we can just specify the font name ...
cairo_pdf(symbolfamily="OpenSymbol")
dev.off()
## ... or equivalently ...
cairo_pdf(symbolfamily=cairoSymbolFont("OpenSymbol"))
dev.off()

## If a font does not use PUA, we must indicate that ...
cairo_pdf(symbolfamily=cairoSymbolFont("Nimbus Sans", usePUA=FALSE))
dev.off()

## End(Not run)
check.options

Set Options with Consistency Checks

Description

Utility function for setting options with some consistency checks. The attributes of the new settings in new are checked for consistency with the model (often default) list in name.opt.

Usage

check.options(new, name.opt, reset = FALSE, assign.opt = FALSE, envir = .GlobalEnv,
              check.attributes = c("mode", "length"),
              override.check = FALSE)

Arguments

new          a named list
name.opt     character with the name of R object containing the default list.
reset        logical; if TRUE, reset the options from name.opt. If there is more than one R object with name name.opt, remove the first one in the search() path.
assign.opt   logical; if TRUE, assign the ...
envir        the environment used for get and assign.
check.attributes
              character containing the attributes which check.options should check.
override.check logical vector of length length(new) (or 1 which entails recycling). For those new[i] where override.check[i] == TRUE, the checks are overridden and the changes made anyway.

Value

A list of components with the same names as the one called name.opt. The values of the components are changed from the new list, as long as these pass the checks (when these are not overridden according to override.check).

Note

Option "names" is exempt from all the checks or warnings, as in the application it can be NULL or a variable-length character vector.

Author(s)

Martin Maechler

See Also

ps.options and pdf.options, which use check.options.
chull

Examples

(L1 <- list(a = 1:3, b = pi, ch = "CH"))
check.options(list(a = 0:2), name.opt = "L1")
check.options(NULL, reset = TRUE, name.opt = "L1")

chull

Compute Convex Hull of a Set of Points

Description

Computes the subset of points which lie on the convex hull of the set of points specified.

Usage

chull(x, y = NULL)

Arguments

x, y coordinate vectors of points. This can be specified as two vectors x and y, a 2-column matrix x, a list x with two components, etc, see xy.coords.

Details

xy.coords is used to interpret the specification of the points. Infinite, missing and NaN values are not allowed.

The algorithm is that given by Eddy (1977).

Value

An integer vector giving the indices of the unique points lying on the convex hull, in clockwise order. (The first will be returned for duplicate points.)

References

See Also

xy.coords, polygon
Examples

X <- matrix(stats::rnorm(2000), ncol = 2)
chull(X)
## Not run:
  # Example usage from graphics package
  plot(X, cex = 0.5)
  hpts <- chull(X)
  hpts <- c(hpts, hpts[1])
  lines(X[hpts, ])
## End(Not run)

__cm__

*Unit Transformation*

Description

Translates from inches to cm (centimeters).

Usage

cm(x)

Arguments

x
  numeric vector

Examples

cm(1)  # = 2.54
## Translate *from* cm *to* inches:
10 / cm(1)  # -> 10cm are 3.937 inches

__col2rgb__

*Color to RGB Conversion*

Description

R color to RGB (red/green/blue) conversion.

Usage

col2rgb(col, alpha = FALSE)

Arguments

col
  vector of any of the three kinds of R color specifications, i.e., either a color name (as listed by colors()), a hexadecimal string of the form "#rrggbb" or "#rrggbbaa" (see rgb), or a positive integer i meaning palette()[i].
alpha
  logical value indicating whether the alpha channel (opacity) values should be returned.
Details

NA (as integer or character) and "NA" mean transparent, which can also be specified as "transparent".

Values of col not of one of these types are coerced: real vectors are coerced to integer and other types to character. (factors are coerced to character: in all other cases the class is ignored when doing the coercion.)

Zero and negative values of col are an error.

Value

An integer matrix with three or four (for alpha = TRUE) rows and number of columns the length of col. If col has names these are used as the column names of the return value.

Author(s)

Martin Maechler and the R core team.

grgb, colors, palette, etc.

The newer, more flexible interface, convertColor().

Examples

col2rgb("peachpuff")
col2rgb(c(blu = "royalblue", reddish = "tomato")) # note: colnames

col2rgb(1:8) # the ones from the palette() (if the default)
col2rgb(paste0("gold", 1:4))
col2rgb("#08a0ff")

## all three kinds of color specifications:
col2rgb(c(red = "red", hex = "#abcdef"))
col2rgb(c(palette = 1:3))

##-- NON-INTRODUCTORY examples --
grC <- col2rgb(paste0("gray", 0:100))
table(print(diff(grC["red",]))) # '2' or '3': almost equidistant

## The 'named' grays are in between ("slate gray" is not gray, strictly)
col2rgb(c(g66 = "gray66", darkg = "dark gray", g67 = "gray67",
g74 = "gray74", gray = "gray", g75 = "gray75",
g82 = "gray82", light = "light gray", g83 = "gray83"))
crgb <- col2rgb(cc <- colors())
colnames(crgb) <- cc
t(crgb) # The whole table

ccodes <- c(256^(2:0) %*% crgb) # = internal codes

## How many names are 'aliases' of each other:
table(tcc <- table(ccodes))

length(uc <- unique(sort(ccodes))) # 502

## All the multiply named colors:
mult <- uc[tcc >= 2]
cl <- lapply(mult, function(m) cc[ccodes == m])
names(cl) <- apply(col2rgb(sapply(cl, function(x)x[1])),
  2, function(n)paste(n, collapse = "","))
utils::str(cl)
## Not run:
if(require(xgobi)) { ## Look at the color cube dynamically :
tc <- t(crgb[, !duplicated(ccodes)])
table(is.gray <- tc[,1] == tc[,2] & tc[,2] == tc[,3]) # (397, 105)
xgobi(tc, color = c(“gold”, “gray”)[1 + is.gray])
}
## End(Not run)

---

**colorRamp**

## Color interpolation

**Description**

These functions return functions that interpolate a set of given colors to create new color palettes (like `topo.colors`) and color ramps, functions that map the interval [0, 1] to colors (like `grey`).

**Usage**

```r
colorRamp(colors, bias = 1, space = c(“rgb”, “Lab”),
  interpolate = c(“linear”, “spline”), alpha = FALSE)
colorRampPalette(colors, ...)
```

**Arguments**

- **colors** colors to interpolate; must be a valid argument to `col2rgb()`.
- **bias** a positive number. Higher values give more widely spaced colors at the high end.
- **space** a character string; interpolation in RGB or CIE Lab color spaces.
- **interpolate** use spline or linear interpolation.
- **alpha** logical: should alpha channel (opacity) values be returned? It is an error to give a true value if space is specified.
- **...** arguments to pass to colorRamp.

**Details**

The CIE Lab color space is approximately perceptually uniform, and so gives smoother and more uniform color ramps. On the other hand, palettes that vary from one hue to another via white may have a more symmetrical appearance in RGB space.

The conversion formulas in this function do not appear to be completely accurate and the color ramp may not reach the extreme values in Lab space. Future changes in the R color model may change the colors produced with `space = “Lab”`. 
Value

colorRamp returns a function with argument a vector of values between 0 and 1 that are mapped to a numeric matrix of RGB color values with one row per color and 3 or 4 columns.

colorRampPalette returns a function that takes an integer argument (the required number of colors) and returns a character vector of colors (see rgb) interpolating the given sequence (similar to heat.colors or terrain.colors).

See Also

Good starting points for interpolation are the “sequential” and “diverging” ColorBrewer palettes in the RColorBrewer package.
splinefun or approxfun are used for interpolation.

Examples

## Both return a *function* :
colorRamp(c("red", "green"))( (0:4)/4 ) ## (x) , x in [0,1]
colorRampPalette(c("blue", "red"))( 4 ) ## (n)
## a ramp in opacity of blue values
colorRampPalette(c(rgb(0,0,1,1), rgb(0,0,1,0)), alpha = TRUE)(8)

require(graphics)
## Here space="rgb" gives palettes that vary only in saturation, 
## as intended.
## With space="Lab" the steps are more uniform, but the hues 
## are slightly purple.
filled.contour(volcano, 
color.palette = 
colorRampPalette(c("red", "white", "blue")),

                           space = "Lab")
filled.contour(m, col = rgb.palette(20))
filled.contour(m, col = Lab.palette(20))

<table>
<thead>
<tr>
<th>colors</th>
<th>Color Names</th>
</tr>
</thead>
</table>

**Description**

Returns the built-in color names which R knows about.

**Usage**

```
colors (distinct = FALSE)
colours(distinct = FALSE)
```

**Arguments**

- `distinct` logical indicating if the colors returned should all be distinct; e.g., "snow" and
  "snow1" are effectively the same point in the (0 : 255)^3 RGB space.

**Details**

These color names can be used with a `col=` specification in graphics functions.

An even wider variety of colors can be created with primitives `rgb`, `hsv` and `hcl`, or the derived
`rainbow`, `heat.colors`, etc.

"transparent" is not a color and so not listed, but it is accepted as a color specification.

**Value**

A character vector containing all the built-in color names.

**See Also**

`palette` for setting the ‘palette’ of colors for `par(col=<num>); rgb, hsv, hcl, gray; rainbow` for a nice example; and `heat.colors, topo.colors` for images.

`col2rgb` for translating to RGB numbers and extended examples.

**Examples**

```
c1 <- colors()
length(c1); c1[1:20]

length(c1. <- colors(TRUE))
## only 502 of the 657 named ones

## -------- Show all named colors and more:
demo("colors")
## --------
```
contourLines

Calculate Contour Lines

Description

Calculate contour lines for a given set of data.

Usage

```r
contourLines(x = seq(0, 1, length.out = nrow(z)),
y = seq(0, 1, length.out = ncol(z)),
z, nlevels = 10,
levels = pretty(range(z, na.rm = TRUE), nlevels))
```

Arguments

- `x`, `y` locations of grid lines at which the values in `z` are measured. These must be in ascending order. By default, equally spaced values from 0 to 1 are used. If `x` is a list, its components `x$x` and `x$y` are used for `x` and `y`, respectively. If the list has component `z` this is used for `z`.
- `z` a matrix containing the values to be plotted (NAs are allowed). Note that `x` can be used instead of `z` for convenience.
- `nlevels` number of contour levels desired **iff** `levels` is not supplied.
- `levels` numeric vector of levels at which to draw contour lines.

Details

`contourLines` draws nothing, but returns a set of contour lines.

There is currently no documentation about the algorithm. The source code is in `R_HOME/src/main/plot3d.c`.

Value

A **list** of contours, each itself a **list** with elements:

- `level` The contour level.
- `x` The x-coordinates of the contour.
- `y` The y-coordinates of the contour.

See Also

- `options("max.contour.segments")` for the maximal complexity of a single contour line.
- `contour`: Its ‘Examples’ demonstrate how `contourLines()` can be drawn and are the same (as those from `contour()`).
Examples

```r
x <- 10*1:nrow(volcano)
y <- 10*1:ncol(volcano)
cl <- contourLines(x, y, volcano)
## summarize the sizes of each the contour lines :
cbind(lev = vapply(cl, `[[`, .5, "level"),
n = vapply(cl, function(l) length(l$x), 1))
z <- outer(-9:25, -9:25)
pretty(range(z), 10) # -300 -200 ... 600 700
utils::str(c2 <- contourLines(z))
# no segments for {-300, 700};
# 2 segments for {-200, -100, 0}.
# 1 segment for 100:600
```

### convertColor

**Convert between Colour Spaces**

**Description**

Convert colours between their representations in standard colour spaces.

**Usage**

```
convertColor(color, from, to, from.ref.white, to.ref.white,
    scale.in = 1, scale.out = 1, clip = TRUE)
```

**Arguments**

- `color`: A matrix whose rows specify colors. The function will also accept a data frame, but will silently convert to a matrix internally.
- `from, to`: Input and output color spaces. See ‘Details’ below.
- `from.ref.white, to.ref.white`: Reference whites or NULL if these are built in to the definition, as for RGB spaces. D65 is the default, see ‘Details’ for others.
- `scale.in, scale.out`: Input is divided by scale.in, output is multiplied by scale.out. Use NULL to suppress scaling when input or output is not numeric.
- `clip`: If TRUE, truncate RGB output to [0,1], FALSE return out-of-range RGB, NA set out of range colors to NaN.

**Details**

Color spaces are specified by objects of class `colorConverter`, created by `colorConverter` or `make.rgb`. Built-in color spaces may be referenced by strings: "XYZ", "sRGB", "Apple RGB", "CIE RGB", "Lab", "Luv". The converters for these colour spaces are in the object `colorspaces`.

The "sRGB" color space is that used by standard PC monitors. "Apple RGB" is used by Apple monitors. "Lab" and "Luv" are approximately perceptually uniform spaces standardized by the Commission Internationale d’Eclairage. "XYZ" is a 1931 CIE standard capable of representing all visible colors (and then some), but not in a perceptually uniform way.
The Lab and Luv spaces describe colors of objects, and so require the specification of a reference ‘white light’ color. Illuminant D65 is a standard indirect daylight, Illuminant D50 is close to direct sunlight, and Illuminant A is the light from a standard incandescent bulb. Other standard CIE illuminants supported are B, C, E and D55. RGB colour spaces are defined relative to a particular reference white, and can be only approximately translated to other reference whites. The von Kries chromatic adaptation algorithm is used for this. Prior to R 3.6, color conversions involving color spaces created with `make.rgb` were carried out assuming a D65 illuminant, irrespective of the actual illuminant used in the creation of the color space. This affected the built-in "CIE RGB" color space.

The RGB color spaces are specific to a particular class of display. An RGB space cannot represent all colors, and the `clip` option controls what is done to out-of-range colors.

For the named color spaces `color` must be a matrix of values in the `from` color space: in particular opaque colors.

**Value**

A 3-column matrix whose rows specify the colors.

**References**

For all the conversion equations http://www.brucelindbloom.com/.

**See Also**

`col2rgb` and `colors` for ways to specify colors in graphics.

`make.rgb` for specifying other colour spaces.

**Examples**

```r
## The displayable colors from four planes of Lab space
ab <- expand.grid(a = (-10:15)*10, 
                   b = (-15:10)*10)
require(graphics); require(stats) # for na.omit
par(mfrow = c(2, 2), mar = .1+c(3, 3, 3, .5), mgp = c(2, .8, 0))
Lab <- cbind(L = 20, ab)
srgb <- convertColor(Lab, from = "Lab", to = "sRGB", clip = NA)
clipped <- attr(na.omit(srgb), "na.action")
srgb[clipped, ] <- 0
cols <- rgb(srgb[, 1], srgb[, 2], srgb[, 3])
image((-10:15)*10, (-15:10)*10, matrix(1:(26*26), ncol = 26), col = cols, 
xlab = "a", ylab = "b", main = "Lab: L=20")
Lab <- cbind(L = 40, ab)
srgb <- convertColor(Lab, from = "Lab", to = "sRGB", clip = NA)
clipped <- attr(na.omit(srgb), "na.action")
srgb[clipped, ] <- 0
cols <- rgb(srgb[, 1], srgb[, 2], srgb[, 3])
image((-10:15)*10, (-15:10)*10, matrix(1:(26*26), ncol = 26), col = cols, 
xlab = "a", ylab = "b", main = "Lab: L=40")
Lab <- cbind(L = 60, ab)
srgb <- convertColor(Lab, from = "Lab", to = "sRGB", clip = NA)
```
clipped <- attr(na.omit(srgb), "na.action")
srgb[clipped, ] <- 0
cols <- rgb(srgb[, 1], srgb[, 2], srgb[, 3])
image((-10:15)*10, (-15:10)*10, matrix(1:(26*26), ncol = 26), col = cols,
      xlab = "a", ylab = "b", main = "Lab: L=60")
Lab <- cbind(L = 80, ab)
srgb <- convertColor(Lab, from = "Lab", to = "sRGB", clip = NA)
clipped <- attr(na.omit(srgb), "na.action")
srgb[clipped, ] <- 0
cols <- rgb(srgb[, 1], srgb[, 2], srgb[, 3])
image((-10:15)*10, (-15:10)*10, matrix(1:(26*26), ncol = 26), col = cols,
      xlab = "a", ylab = "b", main = "Lab: L=80")
cols <- t(col2rgb(palette())); rownames(cols) <- palette(); cols
zapsmall(lab <- convertColor(cols, from = "sRGB", to = "Lab", scale.in = 255))
stopifnot(all.equal(cols, # converting back.. getting the original:
                  round(convertColor(lab, from = "Lab", to = "sRGB", scale.out = 255)),
                  check.attributes = FALSE))

densCols

Colors for Smooth Density Plots

Description
densCols produces a vector containing colors which encode the local densities at each point in a scatterplot.

Usage
densCols(x, y = NULL, nbin = 128, bandwidth,
         colramp = colorRampPalette(blues9[-(1:3)]))
blues9

Arguments

x, y          the x and y arguments provide the x and y coordinates of the points. Any reasonable way of defining the coordinates is acceptable. See the function xy.coords for details. If supplied separately, they must be of the same length.
nbin          numeric vector of length one (for both directions) or two (for x and y separately) specifying the number of equally spaced grid points for the density estimation; directly used as gridsize in bkde2D().
bandwidth      numeric vector (length 1 or 2) of smoothing bandwidth(s). If missing, a more or less useful default is used. bandwidth is subsequently passed to function bkde2D.
colramp        function accepting an integer n as an argument and returning n colors.

Details
densCols computes and returns the set of colors that will be used in plotting, calling bkde2D(*,bandwidth,gridsize = nbin,..) from package KernSmooth.
blues9 is a set of 9 color shades of blue used as the default in plotting.
Value

densCols returns a vector of length nrow(x) that contains colors to be used in a subsequent scatterplot. Each color represents the local density around the corresponding point.

Author(s)

Florian Hahne at FHCRC, originally

See Also

bkde2D from package KernSmooth; further, smoothScatter() (package graphics) which builds on the same computations as densCols.

Examples

```r
x1 <- matrix(rnorm(1e3), ncol = 2)
x2 <- matrix(rnorm(1e3, mean = 3, sd = 1.5), ncol = 2)
x <- rbind(x1, x2)
dcols <- densCols(x)
graphics::plot(x, col = dcols, pch = 20, main = "n = 1000")
```

---

**Control Multiple Devices**

Description

These functions provide control over multiple graphics devices.

Usage

```r
dev.cur()
dev.list()
dev.next(which = dev.cur())
dev.prev(which = dev.cur())
dev.off(which = dev.cur())
dev.set(which = dev.next())
dev.new(..., noRStudioGD = FALSE)
graphics.off()
```

Arguments

- `which` An integer specifying a device number.
- `...` arguments to be passed to the device selected.
- `noRStudioGD` Do not use the RStudio graphics device even if specified as the default device: it does not accept arguments such as width and height.
Details

Only one device is the ‘active’ device: this is the device in which all graphics operations occur. There is a "null device" which is always open but is really a placeholder: any attempt to use it will open a new device specified by `getOption("device")`.

Devices are associated with a name (e.g., "X11" or "postscript") and a number in the range 1 to 63; the "null device" is always device 1. Once a device has been opened the null device is not considered as a possible active device. There is a list of open devices, and this is considered as a circular list not including the null device. `dev.next` and `dev.prev` select the next open device in the appropriate direction, unless no device is open.

dev.off shuts down the specified (by default the current) device. If the current device is shut down and any other devices are open, the next open device is made current. It is an error to attempt to shut down device 1. `graphics.off()` shuts down all open graphics devices. Normal termination of a session runs the internal equivalent of `graphics.off()`.

dev.set makes the specified device the active device. If there is no device with that number, it is equivalent to dev.next. If which = 1 it opens a new device and selects that.

dev.new opens a new device. Normally R will open a new device automatically when needed, but this enables you to open further devices in a platform-independent way. (For which device is used see `getOption("device")`.) Note that care is needed with file-based devices such as pdf and postscript and in that case file names such as ‘Rplots.pdf’, ‘Rplots1.pdf’, . . . , ‘Rplots999.pdf’ are tried in turn. Only named arguments are passed to the device, and then only if they match the argument list of the device. Even so, care is needed with the interpretation of e.g. width, and for the standard bitmap devices `units = "in", res = 72` is forced if neither is supplied but both width and height are.

Value

dev.cur returns a length-one named integer vector giving the number and name of the active device, or 1, the null device, if none is active.

dev.list returns the numbers of all open devices, except device 1, the null device. This is a numeric vector with a `names` attribute giving the device names, or `NULL` if there is no open device.

dev.next and dev.prev return the number and name of the next / previous device in the list of devices. This will be the null device if and only if there are no open devices.

dev.off returns the number and name of the new active device (after the specified device has been shut down).

dev.set returns the number and name of the new active device.

dev.new returns the return value of the device opened, usually invisible `NULL`.

Devices, such as postscript, etc.

layout and its links for setting up plotting regions on the current device.

Examples

```r
## Not run: ## Unix-specific example
x11()
plot(1:10)
x11()
plot(rnorm(10))
dev.set(dev.prev())
```
abline(0, 1) # through the 1:10 points
dev.set(dev.next())
abline(h = 0, col = "gray") # for the residual plot
dev.set(dev.prev())
dev.off(); dev.off() # close the two X devices

## End(Not run)

### dev.capabilities

**Description**

Query the capabilities of the current graphics device.

**Usage**

```r
dev.capabilities(what = NULL)
```

**Arguments**

- `what`  
  a character vector partially matching the names of the components listed in section ‘Value’, or NULL which lists all available capabilities.

**Details**

The capabilities have to be specified by the author of the graphics device, unless they can be deduced from missing hooks. Thus they will often by returned as NA, and may reflect the maximal capabilities of the underlying device where several output formats are supported by one device.

Most recent devices support semi-transparent colours provided the graphics format does (which PostScript does not). On the other hand, relatively few graphics formats support (fully or semi-) transparent backgrounds: generally the latter is found only in PDF and PNG plots.

**Value**

A named list with some or all of the following components, any of which may take value NA:

- `semiTransparency`  
  logical: Does the device support semi-transparent colours?

- `transparentBackground`  
  character: Does the device support (semi)-transparent backgrounds? Possible values are “no”, “fully” (only full transparency) and “semi” (semi-transparent background colours are supported).

- `rasterImage`  
  character: To what extent does the device support raster images as used by `rasterImage` and `grid.raster`? Possible values "no", "yes" and "non-missing" (support only for arrays without any missing values).

- `capture`  
  logical: Does the current device support raster capture as used by `grid.cap`?

- `locator`  
  logical: Does the current device support `locator` and `identify`?

- `events`  
  character: Which events can be generated on this device? Currently this will be a subset of c("MouseDown", "MouseMove", "MouseUp", "Keybd"), but other events may be supported in the future.
dev.flush

See Also
See getGraphicsEvent for details on interactive events.

Examples

dev.capabilities()

dev.capture

Description

dev.capture captures the current contents of a graphics device as a raster (bitmap) image.

Usage

dev.capture(native = FALSE)

Arguments

native Logical. If FALSE the result is a matrix of R color names, if TRUE the output is returned as a nativeRaster object which is more efficient for plotting, but not portable.

Details

Not all devices support capture of the output as raster bitmaps. Typically, only image-based devices do and even not all of them.

Value

NULL if the device does not support capture, otherwise a matrix of color names (for native = FALSE) or a nativeRaster object (for native = TRUE).

dev.flush

Hold or Flush Output on an On-Screen Graphics Device.

Description

This gives a way to hold/flush output on certain on-screen devices, and is ignored by other devices.

Usage

dev.hold(level = 1L)
dev.flush(level = 1L)

Arguments

level Integer >= 0. The amount by which to change the hold level. Negative values will be silently replaced by zero.
Details

Devices which implement this maintain a stack of hold levels: calling `dev.hold` increases the level and `dev.flush` decreases it. Calling `dev.hold` when the hold level is zero increases the hold level and inhibits graphics display. When calling `dev.flush` clears all pending holds the screen display is refreshed and normal operation is resumed.

This is implemented for the cairo-based X11 types with buffering. When the hold level is positive the ‘watch’ cursor is set on the device’s window.

It is available on the quartz device on macOS.

This is implemented for the windows device with buffering selected (the default). When the hold level is positive the ‘busy’ cursor is set on the device’s window.

Value

The current level after the change, invisibly. This is 0 on devices where hold levels are not supported.

dev.interactive

Is the Current Graphics Device Interactive?

Description

Test if the current graphics device (or that which would be opened) is interactive.

Usage

dev.interactive(orNone = FALSE)

deviceIsInteractive(name = NULL)

Arguments

orNone logical: if TRUE, the function also returns TRUE when .Device == "null device" and getOption("device") is among the known interactive devices.

name one or more device names as a character vector, or NULL to give the existing list.

Details

The X11 (Unix), windows (Windows) and quartz (macOS, on-screen types only) are regarded as interactive, together with JavaGD (from the package of the same name) and CairoWin and CairoX11 (from package Cairo). Packages can add their devices to the list by calling deviceIsInteractive.

Value

dev.interactive() returns a logical, TRUE if and only if an interactive (screen) device is in use.

deviceIsInteractive returns the updated list of known interactive devices, invisibly unless name = NULL.

See Also

Devices for the available devices on your platform.
Examples

dev.interactive()
print(deviceIsInteractive(NULL))

---

dev.size

Find Size of Device Surface

Description

Find the dimensions of the device surface of the current device.

Usage

dev.size(units = c("in", "cm", "px"))

Arguments

units

the units in which to return the value – inches, cm, or pixels (device units).

Value

A two-element numeric vector giving width and height of the current device; a new device is opened if there is none, similarly to dev.new().

See Also

The size information in inches can be obtained by par("din"), but this provides a way to access it independent of the graphics sub-system in use. Note that par("din") is only updated when a new plot is started, whereas dev.size tracks the size as an on-screen device is resized.

Examples

dev.size("cm")

---

dev2

Copy Graphics Between Multiple Devices

Description

dev.copy copies the graphics contents of the current device to the device specified by which or to a new device which has been created by the function specified by device (it is an error to specify both which and device). (If recording is off on the current device, there are no contents to copy: this will result in no plot or an empty plot.) The device copied to becomes the current device.

dev.print copies the graphics contents of the current device to a new device which has been created by the function specified by device and then shuts the new device.

dev.copy2eps is similar to dev.print but produces an EPSF output file in portrait orientation (horizontal = FALSE). dev.copy2pdf is the analogue for PDF output.

dev.control allows the user to control the recording of graphics operations in a device. If displaylist is "inhibit" ("enable") then recording is turned off (on). It is only safe to change this at the beginning of a plot (just before or just after a new page). Initially recording is on for screen devices, and off for print devices.
Usage

dev.copy(device, ..., which = dev.next())
dev.print(device = postscript, ...)
dev.copy2eps(...)
dev.copy2pdf(..., out.type = "pdf")
dev.control(displaylist = c("inhibit", "enable"))

Arguments

device A device function (e.g., x11, postscript,...)
...
Arguments to the device function above: for dev.copy2eps arguments to postscript and for dev.copy2pdf, arguments to pdf. For dev.print, this includes which and by default any postscript arguments.
which A device number specifying the device to copy to.
out.type The name of the output device: can be "pdf", or "quartz" (some macOS builds) or "cairo" (Windows and some Unix-alikes, see cairo_pdf).
displaylist A character string: the only valid values are "inhibit" and "enable".

Details

Note that these functions copy the device region and not a plot: the background colour of the device surface is part of what is copied. Most screen devices default to a transparent background, which is probably not what is needed when copying to a device such as png.

For dev.copy2eps and dev.copy2pdf, width and height are taken from the current device unless otherwise specified. If just one of width and height is specified, the other is adjusted to preserve the aspect ratio of the device being copied. The default file name is Rplot.eps or Rplot.pdf, and can be overridden by specifying a file argument.

Copying to devices such as postscript and pdf which need font families pre-specified needs extra care – R is unaware of which families were used in a plot and so they will need to manually specified by the fonts argument passed as part of .... Similarly, if the device to be copied from was opened with a family argument, a suitable family argument will need to be included in ....

The default for dev.print is to produce and print a postscript copy. This will not work unless options("printcmd") is set suitably and you have a PostScript printing system: see postscript for how to set this up. Windows users may prefer to use dev.print(win.print).

dev.print is most useful for producing a postscript print (its default) when the following applies. Unless file is specified, the plot will be printed. Unless width, height and pointsize are specified the plot dimensions will be taken from the current device, shrunk if necessary to fit on the paper. (pointsize is rescaled if the plot is shrunk.) If horizontal is not specified and the plot can be printed at full size by switching its value this is done instead of shrinking the plot region.

If dev.print is used with a specified device (even postscript) it sets the width and height in the same way as dev.copy2eps. This will not be appropriate unless the device specifies dimensions in inches, in particular not for png, jpeg, tiff and bmp unless units = "inches" is specified.

Value

dev.copy returns the name and number of the device which has been copied to.

dev.print, dev.copy2eps and dev.copy2pdf return the name and number of the device which has been copied from.
Note

Most devices (including all screen devices) have a display list which records all of the graphics operations that occur in the device. dev.copy copies graphics contents by copying the display list from one device to another device. Also, automatic redrawing of graphics contents following the resizing of a device depends on the contents of the display list.

After the command dev.control("inhibit"). graphics operations are not recorded in the display list so that dev.copy and dev.print will not copy anything and the contents of a device will not be redrawn automatically if the device is resized.

The recording of graphics operations is relatively expensive in terms of memory so the command dev.control("inhibit") can be useful if memory usage is an issue.

See Also

dev.cur and other dev.xxx functions.

Examples

```r
## Not run:
x11() # on a Unix-alike
plot(rnorm(10), main = "Plot 1")
dev.copy(device = x11)
mtext("Copy 1", 3)
dev.print(width = 6, height = 6, horizontal = FALSE) # prints it
dev.off(dev.prev())
dev.off()
## End(Not run)
```

---

dev2bitmap

**Graphics Device for Bitmap Files via Ghostscript**

Description

bitmap generates a graphics file. dev2bitmap copies the current graphics device to a file in a graphics format.

Usage

```r
bitmap(file, type = "png16m", height = 7, width = 7, res = 72,
       units = "in", pointsize, taa = NA, gaa = NA, ...)

dev2bitmap(file, type = "png16m", height = 7, width = 7, res = 72,
           units = "in", pointsize, ...
           method = c("postscript", "pdf"), taa = NA, gaa = NA)
```

Arguments

- **file** The output file name, with an appropriate extension.
- **type** The type of bitmap.
- **width, height** Dimensions of the display region.
dev2bitmap

<table>
<thead>
<tr>
<th>res</th>
<th>Resolution, in dots per inch.</th>
</tr>
</thead>
<tbody>
<tr>
<td>units</td>
<td>The units in which height and width are given. Can be in (inches), px (pixels), cm or mm.</td>
</tr>
<tr>
<td>pointsize</td>
<td>The pointsize to be used for text: defaults to something reasonable given the width and height</td>
</tr>
<tr>
<td>method</td>
<td>Should the plot be done by postscript or pdf?</td>
</tr>
<tr>
<td>taa, gaa</td>
<td>Number of bits of antialiasing for text and for graphics respectively. Usually 4 (for best effect) or 2. Not supported on all types.</td>
</tr>
</tbody>
</table>

Details

dev2bitmap works by copying the current device to a postscript or pdf device, and post-processing the output file using ghostscript. bitmap works in the same way using a postscript device and post-processing the output as 'printing'.

You will need ghostscript: the full path to the executable can be set by the environment variable R_GSCMD. If this is unset, a GhostScript executable will be looked for by name on your path: on a Unix alike "gs" is used, and on Windows the setting of the environment variable GSC is used, otherwise commands "gswi64c.exe" then "gswin32c.exe" are tried.

The types available will depend on the version of ghostscript, but are likely to include "jpeg","jpegcmkyk","jpeggray","tiffcrcle","tiffg3","tiffg32d","tiffg4","tiffgray", "tiff1zw","tiffpack","tiff12nc","tiff24nc","tiff32nc","png16","png16m","png256", "png48", "pngmono", "pnggray", "pngalpha", "bmp16", "bmp16m" "bmp256", "bmp32b", "bmpgray", "bmpmono".

The default type, "png16m", supports 24-bit colour and anti-aliasing. Type "png256" uses a palette of 256 colours and could give a more compact representation. Monochrome graphs can use "pngmono", or "pnggray" if anti-aliasing is desired. Plots with a transparent background and varying degrees of transparency should use "pngalpha".

Note that for a colour TIFF image you probably want "tiff24nc", which is 8-bit per channel RGB (the most common TIFF format). None of the listed TIFF types support transparency. "tiff32nc" uses 8-bit per channel CMYK, which printers might require.

For formats which contain a single image, a file specification like Rplots%03d.png can be used: this is interpreted by Ghostscript.

For dev2bitmap if just one of width and height is specified, the other is chosen to preserve the aspect ratio of the device being copied. The main reason to prefer method = "pdf" over the default would be to allow semi-transparent colours to be used.

For graphics parameters such as "cra" that need to work in pixels, the default resolution of 72dpi is always used.

On Windows only, paths for file and R_GSCMD which contain spaces are mapped to short names via shortPathName.

Value

None.

Conventions

This section describes the implementation of the conventions for graphics devices set out in the ‘R Internals’ manual. These devices follow the underlying device, so when viewed at the stated res:
• The default device size is 7 inches square.
• Font sizes are in big points.
• The default font family is (for the standard Ghostscript setup) URW Nimbus Sans.
• Line widths are as a multiple of 1/96 inch, with no minimum.
• Circle of any radius are allowed.
• Colours are interpreted by the viewing/printing application.

Note
On Windows, Use of bitmap will leave a temporary file (with file name starting Rbit).
Although using type = "pdfwrite" will work for simple plots, it is not recommended. Either use pdf to produce PDF directly, or call ps2pdf -dAutoRotatePages=/None on the output of postscript: that command is optimized to do the conversion to PDF in ways that these functions are not.

See Also
savePlot, which for windows and X11(type = "cairo") provides a simple way to record a PNG record of the current plot.
postscript, pdf, png, jpeg, tiff and bmp.
To display an array of data, see image.

devAskNewPage

Prompt before New Page

Description
This function can be used to control (for the current device) whether the user is prompted before starting a new page of output.

Usage
devAskNewPage(ask = NULL)

Arguments
ask NULL or a logical value. If TRUE, the user will in future be prompted before a new page of output is started.

Details
If the current device is the null device, this will open a graphics device.
The default argument just returns the current setting and does not change it.
The default value when a device is opened is taken from the setting of options("device.ask.default").
The precise circumstances when the user will be asked to confirm a new page depend on the graphics subsystem. Obviously this needs to be an interactive session. In addition 'recording' needs to be in operation, so only when the display list is enabled (see dev.control) which it usually is only on a screen device.
Value

The current prompt setting before any new setting is applied. Invisibly if ask is logical.

See Also

plot.new, grid.newpage

Description

The following graphics devices are currently available:

windows: On Windows only, the graphics device for Windows (on screen, to printer and to Windows metafile).

pdf: Write PDF graphics commands to a file

postscript: Writes PostScript graphics commands to a file

xfig: Device for XFIG graphics file format

bitmap: bitmap pseudo-device via Ghostscript (if available).

pictex: Writes TeX/PicTeX graphics commands to a file (of historical interest only)

The following devices will be functional if R was compiled to use them (they exist but will return with a warning on other systems):

cairo_pdf, cairo_ps: PDF and PostScript devices based on cairo graphics.

csv: SVG device based on cairo graphics

png: PNG bitmap device

jpeg: JPEG bitmap device

bmp: BMP bitmap device

tiff: TIFF bitmap device

On Unix-alikes (incl. Mac) only:

X11: The graphics device for the X11 windowing system

quartz: The graphics device for the macOS native Quartz 2d graphics system. (This is only functional on macOS where it can be used from the R.app GUI and from the command line: but it will display on the local screen even for a remote session.)

Details

If no device is open, calling any high-level graphics function will cause a device to be opened. Which device is determined by options(“device”) which is initially set as the most appropriate for each platform: a screen device for most interactive use and pdf (or the setting of R_DEFAULT_DEVICE) otherwise. The exception is interactive use under Unix if no screen device is known to be available, when pdf() is used.

It is possible for an R package (or an R front-end such as RStudio) to provide further graphics devices and several packages on CRAN do so. These include other devices outputting SVG and PGF/TiKZ (TeX-based graphics, see http://pgf.sourceforge.net/).
See Also

- **on a Unix-alike:** X11.options, quartz.options,

ps.options and pdf.options for how to customize devices.

dev.interactive, dev.cur, dev.print, graphics.off, image, dev2bitmap.

On Unix-alikes only:
capabilities to see if X11, jpeg, png, tiff, quartz and the cairo-based devices are available.

Examples

```r
## Not run:
## open the default screen device on this platform if no device is
## open
if(dev.cur() == 1) dev.new()
## End(Not run)
```

---

**embedFonts**  
*Embed Fonts in PostScript and PDF*

Description

Runs Ghostscript to process a PDF or PostScript file and embed all fonts in the file.

Usage

```r
embedFonts(file, format, outfile = file,
fontpaths = character(), options = character())
```

Arguments

- **file**  
a character string giving the name of the original file.
- **format**  
the format for the new file (with fonts embedded) given as the name of a
ghostscript output device. If not specified, it is guessed from the suffix of file.
- **outfile**  
the name of the new file (with fonts embedded).
- **fontpaths**  
a character vector giving directories that Ghostscript will search for fonts.
- **options**  
a character vector containing further options to Ghostscript.

Details

This function is not necessary if you just use the standard default fonts for PostScript and PDF output.

If you use a special font, this function is useful for embedding that font in your PostScript or PDF document so that it can be shared with others without them having to install your special font (provided the font licence allows this).

If the special font is not installed for Ghostscript, you will need to tell Ghostscript where the font is, using something like options="-sFONTPATH=path/to/font".
You will need ghostscript: the full path to the executable can be set by the environment variable R_GSCMD. If this is unset, a GhostScript executable will be looked for by name on your path: on a Unix alike "gs" is used, and on Windows the setting of the environment variable GSC is used, otherwise commands "gswi64c.exe" then "gswin32c.exe" are tried.

The format is by default "ps2write", when the original file has a .ps or .eps suffix, or "pdfwrite" when the original file has a .pdf suffix. For versions of Ghostscript before 9.10, format = "pswrite" or format = "epswrite" can be used: as from 9.14 format = "eps2write" is also available. If an invalid device is given, the error message will list the available devices.

Note that Ghostscript may do font substitution, so the font embedded may differ from that specified in the original file.

Some other options which can be useful (see your Ghostscript documentation) are '-dMaxSubsetPct=100', '-dSubsetFonts=true' and '-dEmbedAllFonts=true'.

Value

The shell command used to invoke Ghostscript is returned invisibly. This may be useful for debugging purposes as you can run the command by hand in a shell to look for problems.

postscriptFonts, Devices.

---

extendrange

**Extend a Numerical Range by a Small Percentage**

**Description**

Extends a numerical range by a small percentage, i.e., fraction, on both sides.

**Usage**

`extendrange(x, r = range(x, na.rm = TRUE), f = 0.05)`

**Arguments**

- `x` numeric vector; not used if `r` is specified.
- `r` numeric vector of length 2; defaults to the range of `x`.
- `f` positive number(s) specifying the fraction by which the range should be extended. If longer than one, `f[1]` is used on the left, and `f[2]` on the right.

**Value**

A numeric vector of length 2, `r + c(-f1,f2) * diff(r)`, where f1 is `f[1]` and f2 is `f[2]` or f if it is of length one.

**See Also**

range; pretty which can be considered a sophisticated extension of extendrange.
Examples

```r
x <- 1:5
(r <- range(x)) # 1 5
extendrange(x) # 0.8 5.2
extendrange(x, f= 0.01) # 0.96 5.04

## extend more to the right:
extendrange(x, f=c(.01,.03)) # 0.96 5.12

## Use 'r' if you have it already:
stopifnot(identical(extendrange(r = r),
                     extendrange(x)))
```

getGraphicsEvent

Wait for a mouse or keyboard event from a graphics window

Description

This function waits for input from a graphics window in the form of a mouse or keyboard event.

Usage

```r
getGraphicsEvent(prompt = "Waiting for input",
onMouseDown = NULL, onMouseMove = NULL,
onMouseUp = NULL, onKeybd = NULL,
onIdle = NULL,
consolePrompt = prompt)
setGraphicsEventHandlers(which = dev.cur(), ...)
getGraphicsEventEnv(which = dev.cur())
getGraphicsEventEnv(which = dev.cur(), env)
```

Arguments

- **prompt**: prompt to be displayed to the user in the graphics window
- **onMouseDown**: a function to respond to mouse clicks
- **onMouseMove**: a function to respond to mouse movement
- **onMouseUp**: a function to respond to mouse button releases
- **onKeybd**: a function to respond to key presses
- **onIdle**: a function to call when no events are pending
- **consolePrompt**: prompt to be displayed to the user in the console
- **which**: which graphics device does the call apply to?
- **...**: items including handlers to be placed in the event environment
- **env**: an environment to be used as the event environment
Details

These functions allow user input from some graphics devices (currently only the `windows()`,
`X11(type = "Xlib")` and `X11(type = "cairo")` screen displays in base R). Event handlers may
be installed to respond to events involving the mouse or keyboard.

The functions are related as follows. If any of the first six arguments to `getGraphicsEvent` are
given, then it uses those in a call to `setGraphicsEventHandler` to replace any existing handlers in
the current device. This is for compatibility with pre-2.12.0 R versions. The current normal way to
set up event handlers is to set them using `setGraphicsEventHandler` or `setGraphicsEventEnv` on
one or more graphics devices, and then use `getGraphicsEvent()` with no arguments to retrieve
event data. `getGraphicsEventEnv()` may be used to save the event environment for use later.

The names of the arguments in `getGraphicsEvent` are special. When handling events, the graphics
system will look through the event environment for functions named `onMouseDown`, `onMouseMove`,
`onMouseUp`, `onKeybd`, and `onIdle`, and use them as event handlers. It will use `prompt` for a label on
the graphics device. Two other special names are which, which will identify the graphics device,
and result, where the result of the last event handler will be stored before being returned by
`getGraphicsEvent()`.

The mouse event handlers should be functions with header `function(buttons,x,y)`. The coordi-
nates `x` and `y` will be passed to mouse event handlers in device independent coordinates (i.e., the
lower left corner of the window is `(0, 0)`, the upper right is `(1, 1)`). The `buttons` argument will be
a vector listing the buttons that are pressed at the time of the event, with 0 for left, 1 for middle, and
2 for right.

The keyboard event handler should be a function with header `function(key)`. A single element
character vector will be passed to this handler, corresponding to the key press. Shift and other
modifier keys will have been processed, so `shift-a` will be passed as "A". The following special
keys may also be passed to the handler:

- Control keys, passed as "Ctrl-A", etc.
- Navigation keys, passed as one of "Left", "Up", "Right", "Down", "PgUp", "PgDn", "End", "Home"
- Edit keys, passed as one of "Ins", "Del"
- Function keys, passed as one of "F1", "F2", ...

The idle event handler `onIdle` should be a function with no arguments. If the function is undefined
or `NULL`, then R will typically call a system function which (efficiently) waits for the next event to
appear on a filehandle. Otherwise, the idle event handler will be called whenever the event queue
of the graphics device was found to be empty, i.e. in an infinite loop. This feature is intended to
allow animations to respond to user input, and could be CPU-intensive. Currently, `onIdle` is only
implemented for `X11()` devices.

Note that calling `Sys.sleep()` is not recommended within an idle handler - `Sys.sleep()` re-
moves pending graphics events in order to allow users to move, close, or resize windows while
it is executing. Events such as mouse and keyboard events occurring during `Sys.sleep()` are
lost, and currently do not trigger the event handlers registered via `getGraphicsEvent` or
`setGraphicsEventHandler`.

The event handlers are standard R functions, and will be executed as though called from the event
environment.

In an interactive session, events will be processed until

- one of the event handlers returns a non-`NULL` value which will be returned as the value of
  `getGraphicsEvent`, or
- the user interrupts the function from the console.
When run interactively, `getGraphicsEvent` returns a non-NULL value returned from one of the event handlers. In a non-interactive session, `getGraphicsEvent` will return NULL immediately. It will also return NULL if the user closes the last window that has graphics handlers.

`getGraphicsEventEnv` returns the current event environment for the graphics device, or NULL if none has been set.

`setGraphicsEventEnv` and `setGraphicsEventHandlers` return the previous event environment for the graphics device.

### Examples

```r
# This currently only works on the Windows, X11(type = "Xlib"), and
# X11(type = "cairo") screen devices...
## Not run:
savepar <- par(ask = FALSE)
dragplot <- function(..., xlim = NULL, ylim = NULL, xaxs = "r", yaxs = "r") {
  plot(..., xlim = xlim, ylim = ylim, xaxs = xaxs, yaxs = yaxs)
  startx <- NULL
  starty <- NULL
  prevx <- NULL
  prevy <- NULL
  usr <- NULL

  devset <- function()
    if (dev.cur() != eventEnv$which) dev.set(eventEnv$which)

  dragmousedown <- function(buttons, x, y) {
    startx <<- x
    starty <<- y
    prevx <<- 0
    prevy <<- 0
    devset()
    usr <<- par("usr")
    eventEnv$onMouseMove <- dragmousemove
    NULL
  }

  dragmousemove <- function(buttons, x, y) {
    devset()
    deltay <- diff(grconvertY(c(starty, y), "ndc", "user"))
    deltay <- diff(grconvertY(c(starty, y), "ndc", "user"))
    if (abs(deltay-prevy) > 0) {
      plot(..., xlim = usr[1:2]-deltax, xaxs = "i",
           ylim = usr[3:4]-deltay, yaxs = "i")
      prevx <<- deltay
      prevy <<- deltay
    }
    NULL
  }

 mouseup <- function(buttons, x, y) {
```
eventEnv$onMouseMove <- NULL
)

keydown <- function(key) {
  if (key == "q") return(invisible(1))
  eventEnv$onMouseMove <- NULL
  NULL
}

setGraphicsEventHandlers(prompt = "Click and drag, hit q to quit",
  onMouseDown = dragmousedown,
  onMouseUp = mouseup,
  onKeybd = keydown)

eventEnv <- getGraphicsEventEnv()

dragplot(rnorm(1000), rnorm(1000))
getGraphicsEvent()
par(savepar)

## End(Not run)

---

**gray**

*Gray Level Specification*

**Description**

Create a vector of colors from a vector of gray levels.

**Usage**

```
gray(level, alpha)
grey(level, alpha)
```

**Arguments**

- `level`: a vector of desired gray levels between 0 and 1; zero indicates "black" and one indicates "white".
- `alpha`: the opacity, if specified.

**Details**

The values returned by `gray` can be used with a `col=` specification in graphics functions or in `par`. `grey` is an alias for `gray`.

**Value**

A vector of colors of the same length as `level`.

**See Also**

`rainbow, hsv, hcl, rgb`. 
Examples

gray(0:8 / 8)

---

gray.colors  Gray Color Palette

Description

Create a vector of \( n \) gamma-corrected gray colors.

Usage

gray.colors(n, start = 0.3, end = 0.9, gamma = 2.2, alpha, rev = FALSE)
grey.colors(n, start = 0.3, end = 0.9, gamma = 2.2, alpha, rev = FALSE)

Arguments

- \( n \): the number of gray colors (\( \geq 1 \)) to be in the palette.
- \( \text{start} \): starting gray level in the palette (should be between 0 and 1 where zero indicates "black" and one indicates "white").
- \( \text{end} \): ending gray level in the palette.
- \( \text{gamma} \): the gamma correction.
- \( \text{alpha} \): the opacity, if specified.
- \( \text{rev} \): logical indicating whether the ordering of the colors should be reversed.

Details

The function gray.colors chooses a series of \( n \) gamma-corrected gray levels between \( \text{start} \) and \( \text{end} \): \( \text{seq(start}^{\text{gamma}}, \text{end}^{\text{gamma}}, \text{length} = n)^{(1/\text{gamma})} \). The returned palette contains the corresponding gray colors. This palette is used in barplot.default.

grey.colors is an alias for gray.colors.

Value

A vector of \( n \) gray colors.

See Also

gray, rainbow, palette.

Examples

```r
require(graphics)
pie(rep(1, 12), col = gray.colors(12))
barplot(1:12, col = gray.colors(12))
```
Report Versions of Graphics Software

Description

Report versions of third-party graphics software available on the current platform for R's graphics.

Usage

grSoftVersion()

Value

A named character vector containing at least the elements

cairo     the version of cairographics in use, or "" if cairographics is not available.
cairoFT   "yes" if cairographics is using the FreeType library (and FontConfig); otherwise, "".
pango     the version of pango in use, or "" if pango is not available.

It may also contain the versions of third-party software used by the standard (on Windows), or X11-based (on Unix-alikes) bitmap devices:

libpng    the version of libpng in use, or "" if not available.
jpeg      the version of the JPEG headers used for compilation, or "" if JPEG support was not compiled in.
libtiff    the version of libtiff in use, or "" if not available.

It is conceivable but unlikely that the cairo-based bitmap devices will use different versions linked via cairographics, especially png(type = "cairo-png").

On macOS, if available, the Quartz-based devices will use the system versions of these libraries rather than those reported here.

Unless otherwise stated the reported version is that of the (possibly dynamically-linked) library in use at runtime.

Note that libjpeg-turbo as used on some Linux distributions reports its version as "6.2", the IJG version from which it forked.

See Also

extSoftVersion for versions of non-graphics software.

Examples

grSoftVersion()
hcl

HCL Color Specification

Description
Create a vector of colors from vectors specifying hue, chroma and luminance.

Usage
hcl(h = 0, c = 35, l = 85, alpha, fixup = TRUE)

Arguments
h The hue of the color specified as an angle in the range [0,360]. 0 yields red, 120 yields green 240 yields blue, etc.
c The chroma of the color. The upper bound for chroma depends on hue and luminance.
l A value in the range [0,100] giving the luminance of the colour. For a given combination of hue and chroma, only a subset of this range is possible.
alpha numeric vector of values in the range [0,1] for alpha transparency channel (0 means transparent and 1 means opaque).
fixup a logical value which indicates whether the resulting RGB values should be corrected to ensure that a real color results. if fixup is FALSE RGB components lying outside the range [0,1] will result in an NA value.

Details
This function corresponds to polar coordinates in the CIE-LUV color space. Steps of equal size in this space correspond to approximately equal perceptual changes in color. Thus, hcl can be thought of as a perceptually based version of hsv.
The function is primarily intended as a way of computing colors for filling areas in plots where area corresponds to a numerical value (pie charts, bar charts, mosaic plots, histograms, etc). Choosing colors which have equal chroma and luminance provides a way of minimising the irradiation illusion which would otherwise produce a misleading impression of how large the areas are.
The default values of chroma and luminance make it possible to generate a full range of hues and have a relatively pleasant pastel appearance.
The RGB values produced by this function correspond to the sRGB color space used on most PC computer displays. There are other packages which provide more general color space facilities. Semi-transparent colors (0 < alpha < 1) are supported only on some devices: see rgb.

Value
A vector of character strings which can be used as color specifications by R graphics functions.
Missing or infinite values of any of h, c, l result in NA: such values of alpha are taken as 1 (opaque).

Note
At present there is no guarantee that the colours rendered by R graphics devices will correspond to their sRGB description. It is planned to adopt sRGB as the standard R color description in future.

.demo(hclColors)

---

**Hershey**

**Hershey Vector Fonts in R**

**Description**

If the `family` graphical parameter (see `par`) has been set to one of the Hershey fonts (see ‘Details’) Hershey vector fonts are used to render text.

When using the `text` and `contour` functions Hershey fonts may be selected via the `vfont` argument, which is a character vector of length 2 (see ‘Details’ for valid values). This allows Cyrillic to be selected, which is not available via the font families.

**Usage**

Hershey

**Details**

The Hershey fonts have two advantages:

1. vector fonts describe each character in terms of a set of points; R renders the character by joining up the points with straight lines. This intimate knowledge of the outline of each character means that R can arbitrarily transform the characters, which can mean that the vector fonts look better for rotated text.

2. this implementation was adapted from the GNU libplot library which provides support for non-ASCII and non-English fonts. This means that it is possible, for example, to produce weird plotting symbols and Japanese characters.

**Drawback:**

You cannot use mathematical expressions (`plotmath`) with Hershey fonts.

The Hershey characters are organised into a set of fonts. A particular font is selected by specifying one of the following font families via `par(family)` and specifying the desired font face (plain, bold, italic, bold-italic) via `par(font)`.

```
family       faces available
"HersheySerif"  plain, bold, italic, bold-italic
"HersheySans"   plain, bold, italic, bold-italic
"HersheyScript"  plain, bold
"HersheyGothicEnglish" plain
"HersheyGothicGerman" plain
"HersheyGothicItalian" plain
"HersheySymbol"   plain, bold, italic, bold-italic
"HersheySansSymbol"  plain, italic
```
In the `vfont` specification for the `text` and `contour` functions, the Hershey font is specified by a typeface (e.g., serif or sans serif) and a fontindex or 'style' (e.g., plain or italic). The first element of `vfont` specifies the typeface and the second element specifies the fontindex. The first table produced by `demo(Hershey)` shows the character a produced by each of the different fonts.

The available typeface and fontindex values are available as list components of the variable `Hershey`. The allowed pairs for (typeface,fontindex) are:

```
<table>
<thead>
<tr>
<th>Typeface</th>
<th>Fontindex</th>
</tr>
</thead>
<tbody>
<tr>
<td>serif</td>
<td>plain</td>
</tr>
<tr>
<td>serif</td>
<td>italic</td>
</tr>
<tr>
<td>serif</td>
<td>bold</td>
</tr>
<tr>
<td>serif</td>
<td>bold italic</td>
</tr>
<tr>
<td>serif</td>
<td>cyrillic</td>
</tr>
<tr>
<td>serif</td>
<td>oblique cyrillic</td>
</tr>
<tr>
<td>serif</td>
<td>EUC</td>
</tr>
<tr>
<td>sans serif</td>
<td>plain</td>
</tr>
<tr>
<td>sans serif</td>
<td>italic</td>
</tr>
<tr>
<td>sans serif</td>
<td>bold</td>
</tr>
<tr>
<td>sans serif</td>
<td>bold italic</td>
</tr>
<tr>
<td>script</td>
<td>plain</td>
</tr>
<tr>
<td>script</td>
<td>italic</td>
</tr>
<tr>
<td>script</td>
<td>bold</td>
</tr>
<tr>
<td>gothic english</td>
<td>plain</td>
</tr>
<tr>
<td>gothic german</td>
<td>plain</td>
</tr>
<tr>
<td>gothic italian</td>
<td>plain</td>
</tr>
<tr>
<td>serif symbol</td>
<td>plain</td>
</tr>
<tr>
<td>serif symbol</td>
<td>italic</td>
</tr>
<tr>
<td>serif symbol</td>
<td>bold</td>
</tr>
<tr>
<td>serif symbol</td>
<td>bold italic</td>
</tr>
<tr>
<td>sans serif symbol</td>
<td>plain</td>
</tr>
<tr>
<td>sans serif symbol</td>
<td>italic</td>
</tr>
</tbody>
</table>
```

and the indices of these are available as `Hershey$allowed`.

**Escape sequences:** The string to be drawn can include escape sequences, which all begin with a `'\'`. When R encounters a `'\'`, rather than drawing the `'\'`, it treats the subsequent character(s) as a coded description of what to draw.

One useful escape sequence (in the current context) is of the form: `'\123'`. The three digits following the `'\'` specify an octal code for a character. For example, the octal code for p is 160 so the strings "p" and "\160" are equivalent. This is useful for producing characters when there is not an appropriate key on your keyboard.

The other useful escape sequences all begin with `'\\'`. These are described below. Remember that backslashes have to be doubled in R character strings, so they need to be entered with four backslashes.

**Symbols:** an entire string of Greek symbols can be produced by selecting the HersheySymbol or HersheySansSymbol family or the Serif Symbol or Sans Serif Symbol typeface. To allow Greek symbols to be embedded in a string which uses a non-symbol typeface, there are a set of symbol escape sequences of the form `'\\ab'`. For example, the escape sequence `'\\*a'` produces a Greek alpha. The second table in `demo(Hershey)` shows all of the symbol escape sequences and the symbols that they produce.

**ISO Latin-1:** further escape sequences of the form `'\\ab'` are provided for producing ISO Latin-1 characters. Another option is to use the appropriate octal code. The (non-ASCII) ISO Latin-1
characters are in the range 241...377. For example, \366 produces the character o with an umlaut. The third table in demo(Hershey) shows all of the ISO Latin-1 escape sequences. These characters can be used directly. (Characters not in Latin-1 are replaced by a dot.) Several characters are missing, c-cedilla has no cedilla and ‘sharp s’ (U+00DF, also known as ‘esszett’) is rendered as ss.

**Special Characters:** a set of characters are provided which do not fall into any standard font. These can only be accessed by escape sequence. For example, `\LI` produces the zodiac sign for Libra, and `\JU` produces the astronomical sign for Jupiter. The fourth table in demo(Hershey) shows all of the special character escape sequences.

**Cyrillic Characters:** cyrillic characters are implemented according to the K018-R encoding, and can be used directly in such a locale using the Serif typeface and Cyrillic (or Oblique Cyrillic) fontindex. Alternatively they can be specified via an octal code in the range 300 to 337 for lower case characters or 340 to 377 for upper case characters. The fifth table in demo(Hershey) shows the octal codes for the available Cyrillic characters. Cyrillic has to be selected via a (“serif”,fontindex) pair rather than via a font family.

**Japanese Characters:** 83 Hiragana, 86 Katakana, and 603 Kanji characters are implemented according to the EUC-JP (Extended Unix Code) encoding. Each character is identified by a unique hexadecimal code. The Hiragana characters are in the range 0x2421 to 0x2473, Katakana are in the range 0x2521 to 0x2576, and Kanji are (scattered about) in the range 0x3021 to 0x6d55. When using the Serif typeface and EUC fontindex, these characters can be produced by a pair of octal codes. Given the hexadecimal code (e.g., 0x2421), take the first two digits and add 0x80 and do the same to the second two digits (e.g., 0x21 and 0x24 become 0xa4 and 0xa1), then convert both to octal (e.g., 0xa4 and 0xa1 become 244 and 241). For example, the first Hiragana character is produced by `\244\241`. It is also possible to use the hexadecimal code directly. This works for all non-EUC fonts by specifying an escape sequence of the form `\#J1234`. For example, the first Hiragana character is produced by `\#J2421`. The Kanji characters may be specified in a third way, using the so-called "Nelson Index", by specifying an escape sequence of the form `\#N1234`. For example, the (obsolete) Kanji for ‘one’ is produced by `\#N0001`. demo(Japanese) shows the available Japanese characters.

**Raw Hershey Glyphs:** all of the characters in the Hershey fonts are stored in a large array. Some characters are not accessible in any of the Hershey fonts. These characters can only be accessed via an escape sequence of the form `\#H1234`. For example, the fleur-de-lys is produced by `\#H0746`. The sixth and seventh tables of demo(Hershey) shows all of the available raw glyphs.

**Examples**

Hershey

## for tables of examples, see demo(Hershey)
Description

Create a vector of colors from vectors specifying hue, saturation and value.

Usage

hsv(h = 1, s = 1, v = 1, alpha)

Arguments

h, s, v

numeric vectors of values in the range \([0,1]\) for ‘hue’, ‘saturation’ and ‘value’ to be combined to form a vector of colors. Values in shorter arguments are recycled.

alpha

numeric vector of values in the range \([0,1]\) for alpha transparency channel (0 means transparent and 1 means opaque).

Details

Semi-transparent colors \((0 < \alpha < 1)\) are supported only on some devices: see \texttt{rgb}.

Value

This function creates a vector of colors corresponding to the given values in HSV space. The values returned by \texttt{hsv} can be used with a \texttt{col=} specification in graphics functions or in \texttt{par}.

See Also

\texttt{hcl} for a perceptually based version of \texttt{hsv()}, \texttt{rgb} and \texttt{rgb2hsv} for RGB to HSV conversion; \texttt{rainbow, gray}.

Examples

```r
require(graphics)

hsv(.5, .5, .5)

## Red tones:
# n <- 20; y <- -sin(3*pi*((1:n)-1/2)/n)
# op <- par(mar = rep(1.5, 4))
# plot(y, axes = FALSE, frame.plot = TRUE,
#      xlab = "", ylab = "", pch = 21, cex = 30,
#      bg = rainbow(n, start = .85, end = .1),
#      main = "Red tones")
# par(op)
```
Description

The implementation of Hershey vector fonts provides a large number of Japanese characters (Hiragana, Katakana, and Kanji).

Details

Without keyboard support for typing Japanese characters, the only way to produce these characters is to use special escape sequences: see Hershey.

For example, the Hiragana character for the sound “ka” is produced by ‘\#J242b’ and the Katakana character for this sound is produced by ‘\#J252b’. The Kanji ideograph for “one” is produced by ‘\#J306c’ or ‘\#N0001’.

The output from demo(Japanese) shows tables of the escape sequences for the available Japanese characters.

text(8, 6, "Kanji")
text(8, 8, "English")
Description

These functions specify colour spaces for use in `convertColor`.

Usage

```r
make.rgb(red, green, blue, name = NULL, white = "D65", gamma = 2.2)

colorConverter(toXYZ, fromXYZ, name, white = NULL, vectorized = FALSE)
```

Arguments

- `red`, `green`, `blue`: Chromaticity (xy or xyY) of RGB primaries
- `name`: Name for the colour space
- `white`: Character string specifying the reference white (see ‘Details’.)
- `gamma`: Display gamma (nonlinearity). A positive number or the string "sRGB"
- `fromXYZ`: Function to convert from XYZ tristimulus coordinates to this space
- `toXYZ`: Function to convert from this space to XYZ tristimulus coordinates.
- `vectorized`: Whether `fromXYZ` and `toXYZ` are vectorized internally to handle input color matrices.

Details

An RGB colour space is defined by the chromaticities of the red, green and blue primaries. These are given as vectors of length 2 or 3 in xyY coordinates (the Y component is not used and may be omitted). The chromaticities are defined relative to a reference white, which must be one of the CIE standard illuminants: "A", "B", "C", "D50", "D55", "D60", "E" (usually "D65").

The display gamma is most commonly 2.2, though 1.8 is used for Apple RGB. The sRGB standard specifies a more complicated function that is close to a gamma of 2.2; `gamma = "sRGB"` uses this function.

Colour spaces other than RGB can be specified directly by giving conversions to and from XYZ tristimulus coordinates. The functions should take two arguments. The first is a vector giving the coordinates for one colour. The second argument is the reference white. If a specific reference white is included in the definition of the colour space (as for the RGB spaces) this second argument should be ignored and may be `...`.

As of R 3.6.0 the built in color converters along with `convertColor` were vectorized to process three column color matrices in one call, instead of row by row via `apply`. In order to maintain backwards compatibility, `colorConverter` wraps `fromXYZ` and `toXYZ` in a `apply` loop in case they do not also support matrix inputs. If the `fromXYZ` and `toXYZ` functions you are using operate correctly on the whole color matrix at once instead of row by row, you can set `vectorized=TRUE` for a performance improvement.

Value

An object of class `colorConverter`

scale.in = NULL, scale.out = 255)))
stopifnot(ccv == cols)
msgWindow  

Manipulate a Window

Description

`msgWindow` sends a message to manipulate the specified screen device’s window. With argument `which = -1` it applies to the GUI console (which only accepts the first three actions).

Usage

```r
msgWindow(type = c("minimize", "restore", "maximize", 
                   "hide", "recordOn", "recordOff"),
          which = dev.cur())
```

Arguments

- **type**: action to be taken.
- **which**: a device number, or -1.

See Also

- `bringToTop`, `windows`

n2mfrow  

Compute Default ‘mfrow’ From Number of Plots

Description

Easy setup for plotting multiple figures (in a rectangular layout) on one page. This computes a sensible default for `par(mfrow)`.

Usage

```r
n2mfrow(nr.plots, asp = 1)
```

Arguments

- **nr.plots**: integer; the number of plot figures you’ll want to draw.
- **asp**: positive number; the target aspect ratio (columns / rows) in the output. Was implicitly hardwired to 1; because of that and back compatibility, there is a somewhat discontinuous behavior when varying asp around 1, for `nr.plots <= 12`.

Value

A length-two integer vector (nr, nc) giving the positive number of rows and columns, fulfilling nr * nc >= nr.plots, and currently, for asp = 1, nr >= nc >= 1.
Note

Conceptually, this is a quadratic integer optimization problem, with inequality constraints \( nr \geq 1 \), \( nc \geq 1 \), and \( nr \times plots \geq nr \times nc \) (and possibly \( nr \geq asp \times nc \)), and two objective functions which would have to be combined via a tuning weight, say \( w \), to, e.g., \( (nr \times plots - nr \times nc) + w|nr/nc - asp| \).

The current algorithm is simple and not trying to solve one of these optimization problems.

Author(s)

Martin Maechler; suggestion of asp by Michael Chirico.

require(graphics)
n2mfrow(8) # 3 x 3

n <- 5 ; x <- seq(-2, 2, len = 51)
## suppose now that 'n' is not known (inside function)
op <- par(mfrow = n2mfrow(n))
for (j in 1:n)
  plot(x, x^j, main = substitute(x^ exp, list(exp = j)), type = "l",
       col = "blue")

sapply(1:14, n2mfrow)
sapply(1:14, n2mfrow, asp=16/9)
```

\textbf{nclass} \hspace{1cm} \textit{Compute the Number of Classes for a Histogram}

Description

Compute the number of classes for a histogram.

Usage

\texttt{nclass.Sturges(x)}
\texttt{nclass.scott(x)}
\texttt{nclass.FD(x)}

Arguments

\texttt{x} \hspace{1cm} a data vector.
Details

nclass.Sturges uses Sturges’ formula, implicitly basing bin sizes on the range of the data.

nclass.scott uses Scott’s choice for a normal distribution based on the estimate of the standard error, unless that is zero where it returns 1.

nclass.FD uses the Freedman-Diaconis choice based on the inter-quartile range (IQR(signif(x,5))) unless that’s zero where it uses increasingly more extreme symmetric quantiles up to c(1.511)/512 and if that difference is still zero, reverts to using Scott’s choice.

Value

The suggested number of classes.

References

Examples

```r
set.seed(1)
x <- stats::rnorm(1111)
nclass.Sturges(x)

## Compare them:
NC <- function(x) c(Sturges = nclass.Sturges(x),
                    Scott = nclass.scott(x), FD = nclass.FD(x))
NC(x)
onePt <- rep(1, 11)
NC(onePt) # no longer gives NaN
```
Set or View the Graphics Palette

**Description**

View or manipulate the color palette which is used when `col=` has a numeric index and supporting functions.

**Usage**

```r
palette(value)
palette.pals()
palette.colors(n = NULL, palette = "Okabe-Ito", alpha, recycle = FALSE)
```

**Arguments**

- **value**
  - an optional character vector specifying a new palette (see Details).
- **n**
  - the number of colors to select from a palette. The default `NULL` selects all colors of the given palette.
- **palette**
  - a valid palette name (one of `palette.pals()`). The name is matched to the list of available palettes, ignoring upper vs. lower case, spaces, dashes, etc. in the matching.
- **alpha**
  - an alpha-transparency level in the range \([0,1]\) (0 means transparent and 1 means opaque).
- **recycle**
  - logical indicating what happens in case \(n > \text{length}(\text{palette}(.))\). By default (\(\text{recycle} = \text{FALSE}\)), the result is as for \(n = \text{NULL}\), but with a warning.

**Details**

The `palette()` function gets or sets the current palette, the `palette.pals()` function lists the available predefined palettes, and the `palette.colors()` function selects colors from the predefined palettes.

The color palette and referring to colors by number (see e.g. `par`) was provided for compatibility with S. R extends and improves on the available set of palettes.

If `value` has length 1, it is taken to be the name of a built-in color palette. The available palette names are returned by `palette.pals()`. It is also possible to specify "default".

If `value` has length greater than 1 it is assumed to contain a description of the colors which are to make up the new palette. The maximum size for a palette is 1024 entries.

If `value` is omitted, no change is made to the current palette.

There is only one palette setting for all devices in an R session. If the palette is changed, the new palette applies to all subsequent plotting.

The current palette also applies to re-plotting (for example if an on-screen device is resized or `dev.copy` or `replayPlot` is used). The palette is recorded on the displaylist at the start of each page and when it is changed.
palette

Value

palette() returns a character vector giving the colors from the palette which was in effect. This is invisible unless the argument is omitted.
palette.pals() returns a character vector giving the names of predefined palettes.
palette.colors() returns a vector of R colors.

</tr>
</tbody>
</table>
**Palettes**

**Arguments**

- `n`: the number of colors (≥ 1) to be in the palette.
- `palette`: a valid palette name (one of `hcl.pals()`). The name is matched to the list of available palettes, ignoring upper vs. lower case, spaces, dashes, etc. in the matching.
- `alpha`: an alpha-transparency level in the range [0,1] (0 means transparent and 1 means opaque), see argument `alpha` in `hsv` and `hcl`, respectively. Since R 4.0.0, a `missing`, i.e., not explicitly specified `alpha` is equivalent to `alpha = NULL`, which does not add opacity codes (“FF”) to the individual color hex codes.
- `rev`: logical indicating whether the ordering of the colors should be reversed.
- `fixup`: logical indicating whether the resulting color should be corrected to RGB coordinates in [0,1], see `hcl`.
- `type`: the type of palettes to list: "qualitative", "sequential", "diverging", or "divergingx". `NULL` lists all palettes.
- `s`, `v`: the 'saturation' and 'value' to be used to complete the HSV color descriptions.
- `start`, `end`: the (corrected) hue in [0,1] at which the rainbow begins and ends.

**Details**

All of these functions (except the helper function `hcl.pals()`) create a vector of `n` contiguous colors, either based on the HSV color space (rainbow, heat, terrain, topography, and cyan-magenta colors) or the perceptually-based HCL color space.

HSV (hue-saturation-value) is a simple transformation of the RGB (red-green-blue) space which was therefore a convenient choice for color palettes in many software systems (see also `hsv`). However, HSV colors capture the perceptual properties hue, colorfulness/saturation/chroma, and lightness/brightness/luminance/value only poorly and consequently the corresponding palettes are typically not a good choice for statistical graphics and data visualization.

In contrast, HCL (hue-chroma-luminance) colors are much more suitable for capturing human color perception (see also `hcl`) and better color palettes can be derived based on HCL coordinates. Conceptually, three types of palettes are often distinguished:

- **Qualitative**: For coding categorical information, i.e., where no particular ordering of categories is available and every color should receive the same perceptual weight.
- **Sequential**: For coding ordered/numeric information, i.e., where colors go from high to low (or vice versa).
- **Diverging**: Designed for coding numeric information around a central neutral value, i.e., where colors diverge from neutral to two extremes.

The `hcl.colors` function provides a basic and lean implementation of the pre-specified palettes in the `colorspace` package. In addition to the types above, the functions distinguish “diverging” palettes where the two arms are restricted to be rather balanced as opposed to flexible “divergingx” palettes that combine two sequential palettes without any restrictions. The latter group also includes the cividis palette as it is based on two different hues (blue and yellow) but it is actually a sequential palette (going from dark to light).

The names of all available HCL palettes can be queried with the `hcl.pals` function and they are also visualized by color swatches in the examples. Many of the palettes closely approximate palettes of
the same name from various other packages (including RColorBrewer, rcartocolor, viridis, scico, among others).

The default HCL palette is the widely used viridis palette which is a sequential palette with relatively high chroma throughout so that it also works reasonably well as a qualitative palette. However, while viridis is a rather robust default palette, more suitable HCL palettes are available for most visualizations.

For example, "Dark 3" works well for shading points or lines in up to five groups, "YlGnBu" is a sequential palette similar to "viridis" but with aligned chroma/luminance, and "Green–Brown" or "Blue–Red 3" are colorblind-safe diverging palettes.

Further qualitative palettes are provided in the `palette.colors` function. While the qualitative palettes in `hcl.colors` are always based on the same combination of chroma and luminance, the `palette.colors` vary in chroma and luminance up to a certain degree. The advantage of fixing chroma/luminance is that the perceptual weight of the resulting colors is more balanced. The advantage of allowing variation is that more distinguishable colors can be obtained, especially for viewers with color vision deficiencies.

Note that the `rainbow` function implements the (in-)famous rainbow (or jet) color palette that was used very frequently in many software packages but has been widely criticized for its many perceptual problems. It is specified by a start and end hue with red = 0, yellow = $\frac{1}{6}$, green = $\frac{2}{6}$, cyan = $\frac{3}{6}$, blue = $\frac{4}{6}$, and magenta = $\frac{5}{6}$. However, these are very flashy and unbalanced with respect to both chroma and luminance which can lead to various optical illusions. Also, the hues that are equispaced in RGB space tend to cluster at the red, green, and blue primaries. Therefore, it is recommended to use a suitable palette from `hcl.colors` instead of `rainbow`.

**Value**

A character vector `cv` containing either palette names (for `hcl.pals`) or `n` hex color codes (for all other functions). The latter can be used either to create a user-defined color palette for subsequent graphics by `palette(cv)`, a `col =` specification in graphics functions or in `par`.

---

**pdf**

**PDF Graphics Device**

**Description**

pdf starts the graphics device driver for producing PDF graphics.

**Usage**

```r
pdf(file = if(onefile) "Rplots.pdf" else "Rplot%03d.pdf",
    width, height, onefile, family, title, fonts, version,
    paper, encoding, bg, fg, pointsize, pagecentre, colormodel,
    useDingbats, useKerning, fillOddEven, compress)
```

**Arguments**

- **file**
  - a character string giving the file path. If it is of the form "|cmd", the output is piped to the command given by cmd. If it is NULL, then no external file is created (effectively, no drawing occurs), but the device may still be queried (e.g., for size of text).
  - For use with onefile = FALSE give a C integer format such as "Rplot%03d.pdf" (the default in that case). (See postscript for further details.)
  - Tilde expansion (see path.expand) is done. An input with a marked encoding is converted to the native encoding or an error is given.

- **width, height**
  - the width and height of the graphics region in inches. The default values are 7.

- **onefile**
  - logical: if true (the default) allow multiple figures in one file. If false, generate a file with name containing the page number for each page. Defaults to TRUE, and forced to true if file is a pipe.

- **family**
  - the font family to be used, see postscript. Defaults to "Helvetica".

- **title**
  - title string to embed as the '/Title' field in the file. Defaults to "R Graphics Output".

- **fonts**
  - a character vector specifying R graphics font family names for additional fonts which will be included in the PDF file. Defaults to NULL.
version  a string describing the PDF version that will be required to view the output. This is a minimum, and will be increased (with a warning) if necessary. Defaults to "1.4", but see ‘Details’.

paper  the target paper size. The choices are "a4", "letter", "legal" (or "us") and "executive" (and these can be capitalized), or "a4r" and "usr" for rotated ('landscape'). The default is "special", which means that the width and height specify the paper size. A further choice is "default"; if this is selected, the paper size is taken from the option "papersize" if that is set and as "a4" if it is unset or empty. Defaults to "special".

encoding  the name of an encoding file. See postscript for details. Defaults to "default".

bg  the initial background color to be used. Defaults to "transparent".

fg  the initial foreground color to be used. Defaults to "black".

pointsize  the default point size to be used. Strictly speaking, in bp, that is 1/72 of an inch, but approximately in points. Defaults to 12.

pagecentre  logical: should the device region be centred on the page? – is only relevant for paper != "special". Defaults to TRUE.

colormodel  a character string describing the color model: currently allowed values are "srgb", "gray" (or "grey") and "cmyk". Defaults to "srgb". See section 'Color models'.

useDingbats  logical. Should small circles be rendered via the Dingbats font? Defaults to FALSE. If TRUE, this can produce smaller and better output, but there can font display problems in broken PDF viewers: although this font is one of the 14 guaranteed to be available in all PDF viewers, that guarantee is not always honoured.

For Unix-alikes (including macOS) see the ‘Note’ for a possible fix for some viewers.

useKerning  logical. Should kerning corrections be included in setting text and calculating string widths? Defaults to TRUE.

fillOddEven  logical controlling the polygon fill mode: see polygon for details. Defaults to FALSE.

compress  logical. Should PDF streams be generated with Flate compression? Defaults to TRUE.

Details

All arguments except file default to values given by pdf.options(). The ultimate defaults are quoted in the arguments section.

df() opens the file file and the PDF commands needed to plot any graphics requested are sent to that file.

The file argument is interpreted as a C integer format as used by sprintf, with integer argument the page number. The default gives files ‘Rplot001.pdf’, ‘Rplot999.pdf’, ‘Rplot1000.pdf’, ....

The family argument can be used to specify a PDF-specific font family as the initial/default font for the device. If additional font families are to be used they should be included in the fonts argument.

If a device-independent R graphics font family is specified (e.g., via par(family = ) in the graphics package), the PDF device makes use of the PostScript font mappings to convert the R graphics font family to a PDF-specific font family description. (See the documentation for pdfFonts.)
This device does not embed fonts in the PDF file, so it is only straightforward to use mappings to the font families that can be assumed to be available in any PDF viewer: "Times" (equivalently "serif"), "Helvetica" (equivalently "sans") and "Courier" (equivalently "mono"). Other families may be specified, but it is the user’s responsibility to ensure that these fonts are available on the system and third-party software (e.g., Ghostscript) may be required to embed the fonts so that the PDF can be included in other documents (e.g., LaTeX): see embedFonts. The URW-based families described for postscript can be used with viewers, platform dependently:

**on Unix-alikes** viewers set up to use URW fonts, which is usual with those based on xpdf or Ghostscript.

**on Windows** viewers such as GSView which utilise URW fonts.

Since embedFonts makes use of Ghostscript, it should be able to embed the URW-based families for use with other viewers.

See postscript for details of encodings, as the internal code is shared between the drivers. The native PDF encoding is given in file ‘PDFDoc.enc’.

The PDF produced is fairly simple, with each page being represented as a single stream (by default compressed and possibly with references to raster images). The R graphics model does not distinguish graphics objects at the level of the driver interface.

The version argument declares the version of PDF that gets produced. The version must be at least 1.2 when compression is used, 1.4 for semi-transparent output to be understood, and at least 1.3 if CID fonts are to be used: if any of these features are used the version number will be increased (with a warning). (PDF 1.4 was first supported by Acrobat 5 in 2001; it is very unlikely not to be supported in a current viewer.)

Line widths as controlled by par(lwd = ) are in multiples of 1/96 inch. Multiples less than 1 are allowed. pch = "." with cex = 1 corresponds to a square of side 1/72 inch, which is also the ‘pixel’ size assumed for graphics parameters such as "cra".

The paper argument sets the ‘/MediaBox’ entry in the file, which defaults to width by height. If it is set to something other than "special", a device region of the specified size is (by default) centred on the rectangle given by the paper size: if either width or height is less than 0.1 or too large to give a total margin of 0.5 inch, it is reset to the corresponding paper dimension minus 0.5. Thus if you want the default behaviour of postscript use pdf(paper = "a4r", width = 0, height = 0) to centre the device region on a landscape A4 page with 0.25 inch margins.

When the background colour is fully transparent (as is the initial default value), the PDF produced does not paint the background. Most PDF viewers will use a white canvas so the visual effect is if the background were white. This will not be the case when printing onto coloured paper, though.

**Color models**

The default color model ("srgb") is sRGB. Model "gray" (or "grey") maps sRGB colors to greyscale using perceived luminosity (biased towards green). "cmyk" outputs in CMYK colorspace.

The simplest possible conversion from sRGB to CMYK is used (https://en.wikipedia.org/wiki/CMYK_color_model#Mapping_RGB_to_CMYK), and raster images are output in RGB.

Also available for backwards compatibility is model "rgb" which uses uncalibrated RGB and corresponds to the model used with that name in R prior to 2.13.0. Some viewers may render some plots in that colorspace faster than in sRGB, and the plot files will be smaller.

**Conventions**

This section describes the implementation of the conventions for graphics devices set out in the ‘R Internals’ manual.
• The default device size is 7 inches square.
• Font sizes are in big points.
• The default font family is Helvetica.
• Line widths are as a multiple of 1/96 inch, with a minimum of 0.01 enforced.
• Circles of any radius are allowed. If useDingbats = TRUE, opaque circles of less than 10 big points radius are rendered using char 108 in the Dingbats font: all semi-transparent and larger circles using a Bézier curve for each quadrant.
• Colours are by default specified as sRGB.

At very small line widths, the line type may be forced to solid.

Printing

Except on Windows it is possible to print directly from pdf by something like (this is appropriate for a CUPS printing system):

```r
pdf("|lp -o landscape", paper = "a4r")
```

This forces onefile = TRUE.

Note

If you see problems with PDF output, do remember that the problem is much more likely to be in your viewer than in R. Try another viewer if possible. Symptoms for which the viewer has been at fault are apparent grids on image plots (turn off graphics anti-aliasing in your viewer if you can) and missing or incorrect glyphs in text (viewers silently doing font substitution).

Unfortunately the default viewers on most Linux and macOS systems have these problems, and no obvious way to turn off graphics anti-aliasing.

Acrobat Reader does not use the fonts specified but rather emulates them from multiple-master fonts. This can be seen in imprecise centering of characters, for example the multiply and divide signs in Helvetica. This can be circumvented by embedding fonts where possible. Most other viewers substitute fonts, e.g. URW fonts for the standard Helvetica and Times fonts, and these too often have different font metrics from the true fonts.

Acrobat Reader can be extended by ‘font packs’, and these will be needed for the full use of encodings other than Latin-1 (although they may be offered for download as needed).

On some Unix-alike systems: If useDingbats = TRUE, the default plotting character pch = 1 was displayed in some PDF viewers incorrectly as a "q" character. (These seem to be viewers based on the ‘poppler’ PDF rendering library). This may be due to incorrect or incomplete mapping of font names to those used by the system. Adding the following lines to `~/.fonts.conf` or `/etc/fonts/local.conf` may circumvent this problem, although this has largely been corrected on the affected systems.

```
<fontconfig>
  <alias binding="same">
    <family>ZapfDingbats</family>
    <accept><family>Dingbats</family></accept>
  </alias>
</fontconfig>
```

Some further workarounds for problems with symbol fonts on viewers using ‘fontconfig’ are given in the ‘Cairo Fonts’ section of the help for X11.
On Windows: The TeXworks PDF viewer was one of those which has been seen to fail to display Dingbats (used by e.g. pch = 1) correctly. Whereas on other platforms the problems seen were incorrect output, on Windows points were silently omitted: however recent versions seem to manage to display Dingbats.

There was a different font bug in the pdf.js viewer included in Firefox: that mapped Dingbats to the Symbol font and so displayed symbols such pch = 1 as lambda.

More details of font families and encodings and especially handling text in a non-Latin-1 encoding and embedding fonts can be found in

Examples

```r
## Test function for encodings
TestChars <- function(encoding = "ISOLatin1", ...) {
  pdf(encoding = encoding, ...)
  par(pty = "s")
  plot(c(-1,16), c(-1,16), type = "n", xlab = ",", ylab = ",",
       xaxs = "i", yaxs = "i")
  title(paste("Centred chars in encoding", encoding))
  grid(17, 17, lty = 1)
  for(i in c(32:255)) {
    x <- i %% 16
    y <- i %/% 16
    points(x, y, pch = i)
  }
  dev.off()
}
## there will be many warnings.
TestChars("ISOLatin2")
## this does not view properly in older viewers.
TestChars("ISOLatin2", family = "URWHelvetica")
## works well for viewing in gs-based viewers, and often in xpdf.
```

pdf.options

Auxiliary Function to Set/View Defaults for Arguments of pdf

Description

The auxiliary function pdf.options can be used to set or view (if called without arguments) the default values for some of the arguments to pdf.

pdf.options needs to be called before calling pdf, and the default values it sets can be overridden by supplying arguments to pdf.
Usage

pdf.options(..., reset = FALSE)

Arguments

... arguments width, height, onefile, family, title, fonts, paper, encoding, pointsize, bg, fg, pagecentre, useDingbats, colormodel, fillOddEven and compress can be supplied.
reset logical: should the defaults be reset to their ‘factory-fresh’ values?

Details

If both reset = TRUE and ... are supplied the defaults are first reset to the ‘factory-fresh’ values and then the new values are applied.

Value

A named list of all the defaults. If any arguments are supplied the return values are the old values and the result has the visibility flag turned off.

See Also

pdf, ps.options.

Examples

pdf.options(bg = "pink")
utils::str(pdf.options())
pdf.options(reset = TRUE) # back to factory-fresh

pictex A PiTeX Graphics Driver

Description

This function produces simple graphics suitable for inclusion in TeX and LaTeX documents. It dates from the very early days of R and is for historical interest only.

Usage

pictex(file = "Rplots.tex", width = 5, height = 4, debug = FALSE, bg = "white", fg = "black")

Arguments

file the file path where output will appear. Tilde expansion (see path.expand) is done. An input with a marked encoding is converted to the native encoding or an error is given.
width The width of the plot in inches.
height the height of the plot in inches.
debug should debugging information be printed.
bg the background color for the plot. Ignored.
fg the foreground color for the plot. Ignored.
Details

This driver is much more basic than the other graphics drivers included in R. It does not have any font metric information, so the use of `plotmath` is not supported.

Line widths are ignored except when setting the spacing of line textures. `pch = "."` corresponds to a square of side 1pt.

This device does not support colour (nor does the PicTeX package), and all colour settings are ignored.

Note that text is recorded in the file as-is, so annotations involving TeX special characters (such as ampersand and underscore) need to be quoted as they would be when entering TeX.

Multiple plots will be placed as separate environments in the output file.

Conventions

This section describes the implementation of the conventions for graphics devices set out in the ‘R Internals’ manual.

- The default device size is 5 inches by 4 inches.
- There is no `pointsize` argument: the default size is interpreted as 10 point.
- The only font family is `cmss10`.
- Line widths are only used when setting the spacing on line textures.
- Circle of any radius are allowed.
- Colour is not supported.

Author(s)

This driver was provided around 1996–7 by Valerio Aimale of the Department of Internal Medicine, University of Genoa, Italy.

plotmath  \hspace{2in} Mathematical Annotation in R

### Description

If the `text` argument to one of the text-drawing functions (`text`, `mtext`, `axis`, `legend`) in R is an expression, the argument is interpreted as a mathematical expression and the output will be formatted according to TeX-like rules. Expressions can also be used for titles, subtitles and x- and y-axis labels (but not for axis labels on `persp` plots).

In most cases other language objects (names and calls, including formulas) are coerced to expressions and so can also be used.

### Details

A mathematical expression must obey the normal rules of syntax for any R expression, but it is interpreted according to very different rules than for normal R expressions.

It is possible to produce many different mathematical symbols, generate sub- or superscripts, produce fractions, etc.

The output from `demo(plotmath)` includes several tables which show the available features. In these tables, the columns of grey text show sample R expressions, and the columns of black text show the resulting output.

The available features are also described in the tables below:

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>x + y</td>
<td>x plus y</td>
</tr>
<tr>
<td>x - y</td>

The supported 'scalable delimiters' are | ( [ { and their right-hand versions. "." is equivalent to "": the corresponding delimiter will be omitted. Delimiter || is supported but has the same effect as |. The special delimiters lceil, lfloor, langle (and their right-hand versions) are not scalable.

The symbol font uses Adobe Symbol encoding so, for example, a lower case mu can be obtained either by the special symbol mu or by symbol("m"). This provides access to symbols that have no special symbol name, for example, the universal, or forall, symbol is symbol("\forall"). To see what symbols are available in this way use TestChars(font=5) as given in the examples for points: some are only available on some devices.

Note to TeX users: TeX’s \Upsilon is Upsilon1. TeX’s \varepsilon is close to epsilon, and there is no equivalent of TeX’s \epsilon. TeX’s \varpi is close to omega1. vartheta, varphi and varsigma are allowed as synonyms for theta1, phi1 and sigma1.
sigma1 is also known as stigma, its Unicode name.

Control characters (e.g., `\n`) are not interpreted in character strings in plotmath, unlike normal plotting.

The fonts used are taken from the current font family, and so can be set by `par(family=)` in base graphics, and `gpar(fontfamily=)` in package `grid`.

Note that bold, italic and bolditalic do not apply to symbols, and hence not to the Greek symbols such as μ which are displayed in the symbol font. They also do not apply to numeric constants.

Other symbols

On many OSes and some graphics devices many other symbols are available as part of the standard text font, and all of the symbols in the Adobe Symbol encoding are in principle available via changing the font face or (see ‘Details’) plotmath: see the examples section of `points` for a function to display them. (‘In principle’ because some of the glyphs are missing from some implementations of the symbol font.) Unfortunately, `postscript` and `pdf` have support for little more than European (not Greek) and CJK characters and the Adobe Symbol encoding (and in a few fonts, also Cyrillic characters).

On Unix-alikes: In a UTF-8 locale any Unicode character can be entered, perhaps as a `\uxxxx` or `\Uxxxxxxxx` escape sequence, but the issue is whether the graphics device is able to display the character. The widest range of characters is likely to be available in the `X11` device using cairo: see its help page for how installing additional fonts can help. This can often be used to display Greek letters in bold or italic.

In non-UTF-8 locales there is normally no support for symbols not in the languages for which the current encoding was intended.

On Windows: Any Unicode character can be entered into a text string via a `\uxxxx` escape, or used by number in a call to `points`. The `windows` family of devices can display such characters if they are available in the font in use. This can often be used to display Greek letters in bold or italic.

A good way to both find out which characters are available in a font and to determine the Unicode number is to use the ‘Character Map’ accessory (usually on the ‘Start’ menu under ‘Accessories->System Tools’). You can also copy-and-paste characters from the ‘Character Map’ window to the Rgui console (but not to Rterm).

```

Description

Graphics devices for BMP, JPEG, PNG and TIFF format bitmap files.

Usage

bmp(filename = "Rplot%03d.bmp",
     width = 480, height = 480, units = "px", pointsize = 12,
     bg = "white", res = NA, ...,
     type = c("cairo", "Xlib", "quartz"), antialias)

jpeg(filename = "Rplot%03d.jpeg",
     width = 480, height = 480, units = "px", pointsize = 12,
     quality = 75,
     bg = "white", res = NA, ...,
     type = c("cairo", "Xlib", "quartz"), antialias)

tiff(filename = "Rplot%03d.tiff",
     width = 480, height = 480, units = "px", pointsize = 12,
     compression = c("none", "rle", "lzw", "jpeg", "zip", "lzw+p", "zip+p"),
     bg = "white", res = NA, ...,
     type = c("cairo", "Xlib", "quartz"), antialias)

Arguments

filename the output file path. The page number is substituted if a C integer format is included in the character string, as in the default. (The result must be less than \texttt{PATH\_MAX} characters long, and may be truncated if not. See \texttt{postscript} for further details.) Tilde expansion is performed where supported by the platform. An input with a marked encoding is converted to the native encoding on an error is given.

width the width of the device.

height the height of the device.
units  The units in which height and width are given. Can be px (pixels, the default), in (inches), cm or mm.

pointsize  the default pointsize of plotted text, interpreted as big points (1/72 inch) at res ppi.

bg  the initial background colour: can be overridden by setting par("bg").

quality  the 'quality' of the JPEG image, as a percentage. Smaller values will give more compression but also more degradation of the image.

compression  the type of compression to be used. Ignored for type = "quartz".

res  The nominal resolution in ppi which will be recorded in the bitmap file, if a positive integer. Also used for units other than the default, and to convert points to pixels.

...  for type = "Xlib" only, additional arguments to the underlying X11 device such as fonts or family.

For types "cairo" and "quartz", the family argument can be supplied. See the 'Cairo fonts' section in the help for X11.

For type "cairo", the symbolfamily argument can be supplied. See X11.options.

Details

Plots in PNG and JPEG format can easily be converted to many other bitmap formats, and both can be displayed in modern web browsers. The PNG format is lossless and is best for line diagrams and blocks of colour. The JPEG format is lossy, but may be useful for image plots, for example. BMP is a standard format on Windows. TIFF is a meta-format: the default format written by tiff is lossless and stores RGB (and alpha where appropriate) values uncompressed—such files are widely accepted, which is their main virtue over PNG.

png supports transparent backgrounds: use bg = "transparent". (Not all PNG viewers render files with transparency correctly.) When transparency is in use in the type = "Xlib" variant a very light grey is used as the background and so appears as transparent if used in the plot. This allows opaque white to be used, as in the example. The type = "cairo", type = "cairo-png" and type = "quartz" variants allow semi-transparent colours, including on a transparent or semi-transparent background.

tiff with types "cairo" and "quartz" supports semi-transparent colours, including on a transparent or semi-transparent background. Compression type "zip" is 'deflate (Adobe-style)'. Compression types "lzw+p" and "zip+p" use horizontal differencing ('differencing predictor', section 14 of the TIFF specification) in combination with the compression method, which is effective for continuous-tone images, especially colour ones.

R can be compiled without support for some or all of the types for each of these devices: this will be reported if you attempt to use them on a system where they are not supported. For type = "Xlib" they may not be usable unless the X11 display is available to the owner of the R process.
type = "cairo" requires Cairo 1.2 or later. type = "quartz" uses the quartz device and so is only available where that is (on some macOS builds: see capabilities("aqua")).

By default no resolution is recorded in the file, except for BMP. Viewers will often assume a nominal resolution of 72 ppi when none is recorded. As resolutions in PNG files are recorded in pixels/metre, the reported ppi value will be changed slightly.

For graphics parameters that make use of dimensions in inches (including font sizes in points) the resolution used is res (or 72 ppi if unset).

png will normally use a palette if there are less than 256 colours on the page, and record a 24-bit RGB file otherwise (or a 32-bit ARGB file if type = "cairo" and non-opaque colours are used). However, type = "cairo-png" uses cairographics’ PNG backend which will never use a palette and normally creates a larger 32-bit ARGB file—this may work better for specialist uses with semi-transparent colours.

Quartz-produced PNG and TIFF plots with a transparent background are recorded with a dark grey matte which will show up in some viewers, including Preview on macOS.

Unknown resolutions in BMP files are recorded as 72 ppi.

Value

A plot device is opened: nothing is returned to the R interpreter.

Warnings

Note that by default the width and height values are in pixels not inches. A warning will be issued if both are less than 20.

If you plot more than one page on one of these devices and do not include something like %d for the sequence number in file, the file will contain the last page plotted.

Differences between OSes

These functions are interfaces to three or more different underlying devices.

- On Windows, devices based on plotting to a hidden screen using Windows’ GDI calls.
- On platforms with support for X11, plotting to a hidden X11 display.
- On macOS when working at the console and when R is compiled with suitable support, using Apple’s Quartz plotting system.
- Where support has been compiled in for cairographics, plotting on cairo surfaces. This may use the native platform support for fonts, or it may use fontconfig to support a wide range of font formats.

Inevitably there will be differences between the options supported and output produced. Perhaps the most important are support for antialiased fonts and semi-transparent colours: the best results are likely to be obtained with the cairo- or Quartz-based devices where available.

The default extensions are ‘.jpg’ and ‘.tif’ on Windows, and ‘.jpeg’ and ‘.tiff’ elsewhere.

Conventions

This section describes the implementation of the conventions for graphics devices set out in the ‘R Internals’ manual.

- The default device size is in pixels.
- Font sizes are in big points interpreted at res ppi.
• The default font family is Helvetica.
• Line widths in 1/96 inch (interpreted at res ppi), minimum one pixel for type = "Xlib", 0.01 for type = "cairo".
• For type = "Xlib" circle radii are in pixels with minimum one.
• Colours are interpreted by the viewing application.

For type = "quartz" see the help for quartz.

Note

For type = "Xlib" these devices are based on the X11 device. The colour model used will be that set up by X11.options at the time the first Xlib-based devices was opened (or the first after all such devices have been closed).

Devices, dev.print

capabilities to see if these devices are supported by this build of R, and if type = "cairo" is supported.

bitmap provides an alternative way to generate plots in many bitmap formats that does not depend on accessing the X11 display but does depend on having GhostScript installed.

Examples

## these examples will work only if the devices are available
## and cairo or an X11 display or a macOS display is available.

## copy current plot to a (large) PNG file
## Not run: dev.print(png, file = "myplot.png", width = 1024, height = 768)

png(file = "myplot.png", bg = "transparent")
plot(1:10)
rect(1, 5, 3, 7, col = "white")
dev.off()

## will make myplot1.jpeg and myplot2.jpeg
jpeg(file = "myplot%d.jpeg")
example(rect)
dev.off()
postscript

PostScript Graphics

Description

postscript starts the graphics device driver for producing PostScript graphics.

Usage

postscript(file = if(onefile) "Rplots.ps" else "Rplot%03d.ps",
    onefile, family, title, fonts, encoding, bg, fg,
    width, height, horizontal, pointsize,
    paper, pagecentre, print.it, command,
    colormodel, useKerning, fillOddEven)

Arguments

file a character string giving the file path. If it is "", the output is piped to the command given by the argument command. If it is of the form "|cmd" , the output is piped to the command given by cmd. For use with onefile = FALSE give a printf format such as "Rplot%03d.ps" (the default in that case). The string should not otherwise contain a %: if it is really necessary, use % in the string for % in the file name. A single integer format matching the regular expression "%[#0 +=-]*[0-9.]+[diouxX]" is allowed. Tilde expansion (see path.expand) is done. An input with a marked encoding is converted to the native encoding or an error is given.

onefile logical: if true (the default) allow multiple figures in one file. If false, generate a file name containing the page number for each page and use an EPSF header and no DocumentMedia comment. Defaults to TRUE.

family the initial font family to be used, normally as a character string. See the section 'Families'. Defaults to "Helvetica".

title title string to embed as the Title comment in the file. Defaults to "R Graphics Output".

fonts a character vector specifying additional R graphics font family names for font families whose declarations will be included in the PostScript file and are available for use with the device. See 'Families' below. Defaults to NULL.

encoding the name of an encoding file. Defaults to "default". The latter is interpreted on Unix-alikes as "ISO Latin1.enc" unless the locale is recognized as corresponding to a language using ISO 8859-{2,5,7,13,15} or KOI8-{R,U}. on Windows as "CP1250.enc" (Central European), "CP1251.enc" (Cyrillic), "CP1253.enc" (Greek) or "CP1257.enc" (Baltic) if one of those codepages is in use, otherwise "WinAnsi.enc" (codepage 1252).

The file is looked for in the ‘enc’ directory of package grDevices if the path does not contain a path separator. An extension "enc" can be omitted.

bg the initial background color to be used. If "transparent" (or any other non-opaque colour), no background is painted. Defaults to "transparent".

fg the initial foreground color to be used. Defaults to "black".
width, height  the width and height of the graphics region in inches. Default to 0.
    If paper != "special" and width or height is less than 0.1 or too large to
give a total margin of 0.5 inch, the graphics region is reset to the corresponding
paper dimension minus 0.5.

horizontal  the orientation of the printed image, a logical. Defaults to true, that is landscape
orientation on paper sizes with width less than height.

points  the default point size to be used. Strictly speaking, in bp, that is 1/72 of an inch,
but approximately in points. Defaults to 12.

paper  the size of paper in the printer. The choices are "a4", "letter" (or "us"),
"legal" and "executive" (and these can be capitalized). Also, "special" can
be used, when arguments width and height specify the paper size. A further
choice is "default" (the default): If this is selected, the papersize is taken from
the option "papersize" if that is set and to "a4" if it is unset or empty.

pagecentre  logical: should the device region be centred on the page? Defaults to true.

print.it  logical: should the file be printed when the device is closed? (This only applies
if file is a real file name.) Defaults to false.

command  the command to be used for ‘printing’. Defaults to "default", the value of
option "printcmd". The length limit is 2*PATH_MAX, typically 8096 bytes on
Unix-alikes and 520 bytes on Windows.

colormodel  a character string describing the color model: currently allowed values
as "srgb", "srgb+gray", "rgb", "rgb-nogray", "gray" (or "grey") and
"cmyk". Defaults to "srgb". See section ‘Color models’.

useKerning  logical. Should kerning corrections be included in setting text and calculating
string widths? Defaults to TRUE.

fillOddEven  logical controlling the polygon fill mode: see polygon for details. Default
FALSE.

Details

All arguments except file default to values given by ps.options(). The ultimate defaults are
quoted in the arguments section.

postscript  opens the file file and the PostScript commands needed to plot any graphics requested
are written to that file. This file can then be printed on a suitable device to obtain hard copy.

The file argument is interpreted as a C integer format as used by sprintf, with integer argument
the page number. The default gives files 'Rplot001.ps', . . . , 'Rplot999.ps', 'Rplot1000.ps', . . .

The postscript produced for a single R plot is EPS (Encapsulated PostScript) compatible, and
can be included into other documents, e.g., into LaTeX, using \includegraphics{<filename>}. For
use in this way you will probably want to use setEPS() to set the defaults as horizontal =
FALSE, onefile = FALSE, paper = "special". Note that the bounding box is for the device region:
if you find the white space around the plot region excessive, reduce the margins of the figure region
via par(mar = ).

Most of the PostScript prologue used is taken from the R character vector .ps.prolog. This is
marked in the output, and can be changed by changing that vector. (This is only advisable for
PostScript experts: the standard version is in namespace:grDevices.)

A PostScript device has a default family, which can be set by the user via family. If other font
families are to be used when drawing to the PostScript device, these must be declared when the
device is created via fonts; the font family names for this argument are R graphics font family
names (see the documentation for postscriptFonts).
Line widths as controlled by \texttt{par(lwd = )} are in multiples of 1/96 inch: multiples less than 1 are allowed. \texttt{pch = "."} with \texttt{cex = 1} corresponds to a square of side 1/72 inch, which is also the ‘pixel’ size assumed for graphics parameters such as "cra".

When the background colour is fully transparent (as is the initial default value), the PostScript produced does not paint the background. Almost all PostScript viewers will use a white canvas so the visual effect is if the background were white. This will not be the case when printing onto coloured paper, though.

**Families**

Font families are collections of fonts covering the five font faces, (conventionally plain, bold, italic, bold-italic and symbol) selected by the graphics parameter \texttt{par(font = )} or the grid parameter \texttt{gpar(fontface = )}. Font families can be specified either as an an initial/default font family for the device via the family argument or after the device is opened by the graphics parameter \texttt{par(family = )} or the grid parameter \texttt{gpar(fontfamily = )}. Families which will be used in addition to the initial family must be specified in the \texttt{fonts} argument when the device is opened.

Font families are declared via a call to \texttt{postscriptFonts}.

The argument \texttt{family} specifies the initial/default font family to be used. In normal use it is one of "AvantGarde", "Bookman", "Courier", "Helvetica", "Helvetica-Narrow", "NewCenturySchoolbook", "Palatino" or "Times", and refers to the standard Adobe PostScript fonts families of those names which are included (or cloned) in all common PostScript devices. Many PostScript emulators (including those based on ghostscript) use the URW equivalents of these fonts, which are "URWGothic", "URWBookman", "NimbusMon", "NimbusSan", "NimbusSanCond", "CenturySch", "URWPalladio" and "NimbusRom" respectively. If your PostScript device is using URW fonts, you will obtain access to more characters and more appropriate metrics by using these names. To make these easier to remember, "URWHelvetica" == "NimbusSan" and "URWTimes" == "NimbusRom" are also supported.

Another type of family makes use of CID-keyed fonts for East Asian languages – see \texttt{postscriptFonts}.

The family argument is normally a character string naming a font family, but family objects generated by \texttt{Type1Font} and \texttt{CIDFont} are also accepted. For compatibility with earlier versions of \texttt{R}, the initial family can also be specified as a vector of four or five afm files.

Note that \texttt{R} does not embed the font(s) used in the PostScript output: see \texttt{embedFonts} for a utility to help do so.

Viewers and embedding applications frequently substitute fonts for those specified in the family, and the substitute will often have slightly different font metrics. \texttt{useKerning = TRUE} spaces the letters in the string using kerning corrections for the intended family: this may look uglier than \texttt{useKerning = FALSE}.

**Encodings**

Encodings describe which glyphs are used to display the character codes (in the range 0–255). Most commonly \texttt{R} uses ISOLatin1 encoding, and the examples for \texttt{text} are in that encoding. However, the encoding used on machines running \texttt{R} may well be different, and by using the encoding argument the glyphs can be matched to encoding in use. This suffices for European and Cyrillic languages, but not for East Asian languages. For the latter, composite CID fonts are used. These fonts are useful for other languages: for example they may contain Greek glyphs. (The rest of this section applies only when CID fonts are not used.)

None of this will matter if only ASCII characters (codes 32–126) are used as all the encodings (except "TeXtext") agree over that range. Some encodings are supersets of ISOLatin1,
too. However, if accented and special characters do not come out as you expect, you may need to change the encoding. Some other encodings are supplied with R: "WinAnsi.enc" and "MacRoman.enc" correspond to the encodings normally used on Windows and Classic Mac OS (at least by Adobe), and "PDFDoc.enc" is the first 256 characters of the Unicode encoding, the standard for PDF. There are also encodings "ISOLatin2.enc", "CP1250.enc", "ISOLatin7.enc" (ISO 8859-13), "CP1257.enc", and "ISOLatin9.enc" (ISO 8859-15), "Cyrillic.enc" (ISO 8859-5), "KOI8-R.enc", "KOI8-U.enc", "CP1251.enc", "Greek.enc" (ISO 8859-7) and "CP1253.enc". Note that many glyphs in these encodings are not in the fonts corresponding to the standard families. (The Adobe ones for all but Courier, Helvetica and Times cover little more than Latin-1, whereas the URW ones also cover Latin-2, Latin-7, Latin-9 and Cyrillic but no Greek. The Adobe exceptions cover the Latin character sets, but not the Euro.)

If you specify the encoding, it is your responsibility to ensure that the PostScript font contains the glyphs used. One issue here is the Euro symbol which is in the WinAnsi and MacRoman encodings but may well not be in the PostScript fonts. (It is in the URW variants; it is not in the supplied Adobe Font Metric files.)

There is an exception. Character 45 ('-') is always set as minus (its value in Adobe ISOLatin1) even though it is hyphen in the other encodings. Hyphen is available as character 173 (octal 0255) in all the Latin encodings, Cyrillic and Greek. (This can be entered as "\uaed" in a UTF-8 locale.) There are some discrepancies in accounts of glyphs 39 and 96: the supplied encodings (except CP1250 and CP1251) treat these as 'quoteright' and 'quoteleft' (rather than 'quotesingle'/'acute' and 'grave' respectively), as they are in the Adobe documentation.

TeX fonts

TeX has traditionally made use of fonts such as Computer Modern which are encoded rather differently, in a 7-bit encoding. This encoding can be specified by encoding = "TeXtext.enc", taking care that the ASCII characters < > \ _ { } are not available in those fonts.

There are supplied families "ComputerModern" and "ComputerModernItalic" which use this encoding, and which are only supported for postscript (and not pdf). They are intended to use with the Type 1 versions of the TeX CM fonts. It will normally be possible to include such output in TeX or LaTeX provided it is processed with dvips -Ppdf -j0 or the equivalent on your system. (-j0 turns off font subsetting.) When family = "ComputerModern" is used, the italic/bold-italic fonts used are slanted fonts (cmsl10 and cmbxsl10). To use text italic fonts instead, set family = "ComputerModernItalic".

These families use the TeX math italic and symbol fonts for a comprehensive but incomplete coverage of the glyphs covered by the Adobe symbol font in other families. This is achieved by special-casing the postscript code generated from the supplied ‘CM_symbol_10.afm’.

Color models

The default color model ("srgb") is sRGB.

The alternative "srgb+gray" uses sRGB for colors, but with pure gray colors (including black and white) expressed as greyscales (which results in smaller files and can be advantageous with some printer drivers). Conversely, its files can be rendered much slower on some viewers, and there can be a noticeable discontinuity in color gradients involving gray or white.

Other possibilities are "gray" (or "grey") which used only greyscales (and converts other colours to a luminance), and "cmyk". The simplest possible conversion from sRGB to CMYK is used (https://en.wikipedia.org/wiki/CMYK_color_model#Mapping_RGB_to_CMYK), and raster images are output in RGB.
Color models provided for backwards compatibility are "rgb" (which is RGB+gray) and "rgb-nogray" which use uncalibrated RGB (as used in R prior to 2.13.0). These result in slightly smaller files which may render faster, but do rely on the viewer being properly calibrated.

**Printing**

A postscript plot can be printed via `postscript` in two ways.

1. Setting `print.it = TRUE` causes the command given in argument `command` to be called with argument "file" when the device is closed. Note that the plot file is not deleted unless `command` arranges to delete it.

2. `file = ""` or `file = "|cmd"` can be used to print using a pipe. Failure to open the command will probably be reported to the terminal but not to R, in which case close the device by `dev.off` immediately.

On Windows the default "printcmd" is empty and will give an error if `print.it = TRUE` is used. Suitable commands to spool a PostScript file to a printer can be found in `RedMon` suite available from [http://pages.cs.wisc.edu/~ghost/index.html](http://pages.cs.wisc.edu/~ghost/index.html). The command will be run in a minimized window. GSView 4.x provides `gsprint.exe` which may be more convenient (it requires Ghostscript version 6.50 or later).

**Conventions**

This section describes the implementation of the conventions for graphics devices set out in the 'R Internals' manual.

- The default device size is 7 inches square.
- Font sizes are in big points.
- The default font family is Helvetica.
- Line widths are as a multiple of 1/96 inch, with a minimum of 0.01 enforced.
- Circle of any radius are allowed.
- Colours are by default specified as sRGB.

At very small line widths, the line type may be forced to solid.

Raster images are currently limited to opaque colours.

**Note**

If you see problems with postscript output, do remember that the problem is much more likely to be in your viewer than in R. Try another viewer if possible. Symptoms for which the viewer has been at fault are apparent grids on image plots (turn off graphics anti-aliasing in your viewer if you can) and missing or incorrect glyphs in text (viewers silently doing font substitution).

Unfortunately the default viewers on most Linux and macOS systems have these problems, and no obvious way to turn off graphics anti-aliasing.

**Author(s)**

Support for Computer Modern fonts is based on a contribution by Brian D’Urso <durso@hussle.harvard.edu>.

`postscriptFonts`, `Devices`, and `check.options` which is called from both `ps.options` and `postscript`.

cairo_ps for another device that can produce PostScript.

More details of font families and encodings and especially handling text in a non-Latin-1 encoding and embedding fonts can be found in

Examples

```r
require(graphics)

## Not run:
# open the file "foo.ps" for graphics output
postscript("foo.ps")
# produce the desired graph(s)
dev.off()  # turn off the postscript device

## On Unix-alikes only:
postscript("|lp -dlw")
# produce the desired graph(s)
dev.off()  # plot will appear on printer

## On Windows:
options(printcmd = \'\redpr -P"\printhost\l\w"\')
postscript(file = tempfile("Rps."), print.it = TRUE)
# produce the desired graph(s)
dev.off()  # send plot file to the printer
## alternative using GSView 4.x:
options(printcmd = \'/\GhostGum/gsview/gsprint -query\')

# for URW PostScript devices
postscript("foo.ps", family = "NimbusSan")

## for inclusion in Computer Modern TeX documents, perhaps
postscript("cm_test.eps", width = 4.0, height = 3.0,
  horizontal = FALSE, onefile = FALSE, paper = "special",
  family = "ComputerModern", encoding = "TeXtext.enc")
# The resultant postscript file can be used by dvips -Ppfb -j0.

## To test out encodings, you can use
TestChars <- function(encoding = "ISOLatin1", family = "URWHelvetica")
{
  postscript(encoding = encoding, family = family)
  par(pty = "s")
  plot(c(-1,16), c(-1,16), type = "n", xlab = "", ylab = "",
    xaxs = "i", yaxs = "i")
  title(paste("Centred chars in encoding", encoding))
  grid(17, 17, lty = 1)
}
```
postscriptFonts

Description

These functions handle the translation of an R graphics font family name to a PostScript or PDF font description, used by the postscript or pdf graphics devices.

Usage

postscriptFonts(...)
pdffonts(...)

Arguments

... either character strings naming mappings to display, or named arguments specifying mappings to add or change.

Details

If these functions are called with no argument they list all the existing mappings, whereas if they are called with named arguments they add (or change) mappings.

A PostScript or PDF device is created with a default font family (see the documentation for postscript), but it is also possible to specify a font family when drawing to the device (for example, see the documentation for "family" in par and for "fontfamily" in gpar in the grid package).

The font family sent to the device is a simple string name, which must be mapped to a set of PostScript fonts. Separate lists of mappings for postscript and pdf devices are maintained for the current R session and can be added to by the user.

The postscriptFonts and pdffonts functions can be used to list existing mappings and to define new mappings. The Type1Font and CIDFont functions can be used to create new mappings, when the xxxFonts function is used to add them to the database. See the examples.

Default mappings are provided for three device-independent family names: "sans" for a sans-serif font (to "Helvetica"), "serif" for a serif font (to "Times") and "mono" for a monospaced font (to "Courier").

```r
for(i in c(32:255)) {
  x <- i %% 16
  y <- i %/% 16
  points(x, y, pch = i)
}
dev.off()
}
## there will be many warnings. We use URW to get a complete enough
## set of font metrics.
TestChars()
TestChars("ISOLatin2")
TestChars("WinAnsi")

## End(Not run)
```
Mappings for a number of standard Adobe fonts (and URW equivalents) are also provided: "AvantGarde", "Bookman", "Courier", "Helvetica", "Helvetica-Narrow", "NewCenturySchoolbook", "Palatino" and "Times"; "URW Gothic", "URW Bookman", "Nimbus Mon", "Nimbus Sans" (synonym "URW Helvetica"), "Nimbus Sans Cond", "Century Sch", "URW Palladio" and "Nimbus Rom" (synonym "URW Times").

There are also mappings for "Computer Modern", "Computer Modern Italic" and "Arial MT" (Monotype Arial).

Finally, there are some default mappings for East Asian locales described in a separate section. The specification of font metrics and encodings is described in the help for the `postscriptFonts` function.

The fonts are not embedded in the resulting PostScript or PDF file, so software including the PostScript or PDF plot file should either embed the font outlines (usually from ".pfb" or ".pfa" files) or use DSC comments to instruct the print spooler or including application to do so (see also `embedFonts`).

A font family has both an R-level name, the argument name used when `postscriptFonts` was called, and an internal name, the family component. These two names are the same for all the pre-defined font families.

Once a font family is in use it cannot be changed. ‘In use’ means that it has been specified via a family or fonts argument to an invocation of the same graphics device already in the R session. (For these purposes `xfig` counts the same as `postscript` but only uses some of the predefined mappings.)

**Value**

A list of one or more font mappings.

**East Asian fonts**

There are some default mappings for East Asian locales: "Japan1", "Japan1 Hei Min", "Japan1 Gothic BBB", and "Japan1 Ryumin" for Japanese; "Korea1" and "Korea1 deb" for Korean; "GB1" (Simplified Chinese) for mainland China and Singapore; "CNS1" (Traditional Chinese) for Hong Kong and Taiwan.

These refer to the following fonts:

- **Japan1 (PS)**: HeiseiKakuGo-W5 (Linotype Japanese printer font)
- **Japan1 (PDF)**: KozMinPro-Regular-Acro (from Adobe Reader 7.0 Japanese Font Pack)
- **Japan1 Hei Min (PS)**: HeiseiMin-W3 (Linotype Japanese printer font)
- **Japan1 Hei Min (PDF)**: HeiseiMin-W3-Acro (from Adobe Reader 7.0 Japanese Font Pack)
- **Japan1 Gothic BBB**: GothicBBB-Medium (Japanese-market PostScript printer font)
- **Japan1 Ryumin**: Ryumin-Light (Japanese-market PostScript printer font)
- **Korea1 (PS)**: Baekmuk-Batang (TrueType font found on some Linux systems)
- **Korea1 (PDF)**: HYSMyeongJoStd-Medium-Acro (from Adobe Reader 7.0 Korean Font Pack)
- **Korea1 deb (PS)**: Batang-Regular
another name for Baekmuk-Batang
KoreanDeb (PDF) HYGothic-Medium-Acro
from Adobe Reader 4.0 Korean Font Pack
GB1 (PS) BousungEG-Light-GB
TrueType font found on some Linux systems
GB1 (PDF) STSong-Light-Acro
from Adobe Reader 7.0 Simplified Chinese Font Pack
CNS1 (PS) MOESung-Regular
Ken Lunde’s CJKV resources
CNS1 (PDF) MSungStd-Light-Acro
from Adobe Reader 7.0 Traditional Chinese Font Pack

BousungEG-Light-GB can be found at ftp://ftp.gnu.org/pub/non-gnu/
com/pub/examples/nutshell/cjkv/adobe/samples/. These will need to be installed or other-
wise made available to the postscript/PDF interpreter such as ghostscript (and not all interpreters
can handle TrueType fonts).

You may well find that your postscript/PDF interpreters has been set up to provide aliases for many of
these fonts. For example, ghostscript on Windows can optionally be installed to map common
East Asian fonts names to Windows TrueType fonts. (You may want to add the \-Acro versions as well.)

Adding a mapping for a CID-keyed font is for gurus only.

Author(s)
Support for Computer Modern fonts is based on a contribution by Brian D’Urso.

pdfFonts("Jp_UCS-2" = "Jp_UCS-2")
names(pdfFonts())
Pretty Breakpoints for Date-Time Classes

Description

Compute a sequence of about n+1 equally spaced 'nice' values which cover the range of the values in x, possibly of length one, when min.n = 0 and there is only one unique x.

Usage

```r
## S3 method for class 'Date'
pretty(x, n = 5, min.n = n %/% 2, sep = " ", ...)  
## S3 method for class 'POSIXt'
pretty(x, n = 5, min.n = n %/% 2, sep = " ", ...)  
```

Arguments

- `x` an object of class "Date" or "POSIXt" (i.e., "POSIXct" or "POSIXlt").
- `n` integer giving the desired number of intervals.
- `min.n` nonnegative integer giving the minimal number of intervals.
- `sep` character string, serving as a separator for certain formats (e.g., between month and year).
- `...` further arguments for compatibility with the generic, ignored.

Value

A vector (of the suitable class) of locations, with attribute "labels" giving corresponding formatted character labels.

See Also

`pretty` for the default method.

Examples

```r
pretty(Sys.Date())  
pretty(Sys.time(), n = 10)  
pretty(as.Date("2000-03-01")) # R 1.0.0 came in a leap year  

## time ranges in diverse scales:% also in ../../reg-tests-1c.R  
require(stats)  
steps <- setNames(c("10 secs", "1 min", "5 mins", "30 mins", "6 hours", "12 hours",  
                    "1 DSTday", "2 weeks", "1 month", "6 months", "1 year",  
                    "10 years", "50 years", "1000 years"),  
x <- as.POSIXct("2002-02-02 02:02")  
lapply(steps,  
    function(s) {  
        at <- pretty(seq(x, by = s, length = 2), n = 5)  
        attr(at, "labels")  
    })  
```
ps.options

Auxiliary Function to Set/View Defaults for Arguments of postscript

Description

The auxiliary function ps.options can be used to set or view (if called without arguments) the
default values for some of the arguments to postscript.

ps.options needs to be called before calling postscript, and the default values it sets can be
overridden by supplying arguments to postscript.

Usage

ps.options(..., reset = FALSE, override.check = FALSE)

setEPS(...)

setPS(...)

Arguments

... arguments onefile, family, title, fonts, encoding, bg, fg, width, height, horizontal, pointsize, paper, pagecentre, print.it, command, colormodel and fillOddEven can be supplied. onefile, horizontal and paper are ignored for setEPS and setPS.

reset logical: should the defaults be reset to their ‘factory-fresh’ values?

override.check logical argument passed to check.options. See the Examples.

Details

If both reset = TRUE and ... are supplied the defaults are first reset to the ‘factory-fresh’ values
and then the new values are applied.

For backwards compatibility argument append is accepted but ignored with a warning.

setEPS and setPS are wrappers to set defaults appropriate for figures for inclusion in documents
(the default size is 7 inches square unless width or height is supplied) and for spooling to a
PostScript printer respectively. For historical reasons the latter is the ultimate default.

Value

A named list of all the previous defaults. If ... or reset = TRUE is supplied the result has the
visibility flag turned off.

See Also

postscript, pdf.options
Examples

```r
ps.options(bg = "pink")
utils::str(ps.options())
```

```r
### ---- error checking of arguments: ----
ps.options(width = 0:12, onefile = 0, bg = pi)
# override the check for 'width', but not 'bg':
ps.options(width = 0:12, bg = pi, override.check = c(TRUE, FALSE))
utils::str(ps.options())
ps.options(reset = TRUE) # back to factory-fresh
```

---

quartz

### macOS Quartz Device

Description

quartz starts a graphics device driver for the macOS system. It supports plotting both to the screen (the default) and to various graphics file formats.

Usage

```r
quartz(title, width, height, pointsize, family, antialias, type,
       file = NULL, bg, canvas, dpi)
```

```r
quartz.options(..., reset = FALSE)
```

```r
quartz.save(file, type = "png", device = dev.cur(), dpi = 100, ...)
```

Arguments

- **title**: title for the Quartz window (applies to on-screen output only), default "Quartz %d". A C-style format for an integer will be substituted by the device number (see the file argument to `postscript` for further details).
- **width**: the width of the plotting area in inches. Default 7.
- **height**: the height of the plotting area in inches. Default 7.
- **pointsize**: the default pointsize to be used. Default 12.
- **family**: this is the family name of the font that will be used by the device. Default "Arial". This will be the base name of a font as shown in Font Book.
- **antialias**: whether to use antialiasing. Default TRUE.
- **type**: the type of output to use. See ‘Details’ for more information. Default "native".
- **file**: an optional target for the graphics device. The default, NULL, selects a default name where one is needed. See ‘Details’ for more information.
- **bg**: the initial background colour to use for the device. Default "transparent". An opaque colour such as "white" will normally be required on off-screen types that support transparency such as "png" and "tiff".
- **canvas**: canvas colour to use for an on-screen device. Default "white", and will be forced to be an opaque colour.
- **dpi**: resolution of the output. The default (NA_real) for an on-screen display defaults to the resolution of the main screen, and to 72 dpi otherwise. See ‘Details’.
Any of the arguments to `quartz` except file.

- **reset**: logical: should the defaults be reset to their defaults?
- **device**: device number to copy from.

### Details

The defaults for all but one of the arguments of `quartz` are set by `quartz.options`: the ‘Arguments’ section gives the ‘factory-fresh’ defaults.

The Quartz graphics device supports a variety of output types. On-screen output types are "" or "native" or "Cocoa". Off-screen output types produce output files and utilize the file argument. `type = "pdf"` gives PDF output. The following bitmap formats may be supported (depending on the OS version): "png", "jpeg", "jpg", "jpeg2000", "tif", "tiff", "gif", "psd" (Adobe Photoshop), "bmp" (Windows bitmap), "sgi" and "pict".

The file argument is used for off-screen drawing. The actual file is only created when the device is closed (e.g., using `dev.off()`). For the bitmap devices, the page number is substituted in the character string, e.g. `Rplot%03d.png`. (The result must be less than PATH_MAX characters long, and may be truncated if not. See `postscript` for further details.) If a file argument is not supplied, the default is `Rplots.pdf` or `Rplot%03d`. `type`. Tilde expansion (see `path.expand`) is done.

If a device-independent R graphics font family is specified (e.g., via `par(family =)` in the graphics package), the Quartz device makes use of the Quartz font database (see `quartzFonts`) to convert the R graphics font family to a Quartz-specific font family description. The default conversions are (MonoType TrueType versions of) Helvetica for sans, Times-Roman for serif and Courier for mono.

On-screen devices are launched with a semi-transparent canvas. Once a new plot is created, the canvas is first painted with the canvas colour and then the current background colour (which can be transparent or semi-transparent). Off-screen devices have no canvas colour, and so start with a transparent background where possible (e.g., `type = "png"` and `type = "tiff"`) – otherwise it appears that a solid white canvas is assumed in the Quartz code. PNG and TIFF files are saved with a dark grey matte which will show up in some viewers, including Preview.

`title` can be used for on-screen output. It must be a single character string with an optional integer printf-style format that will be substituted by the device number. It is also optionally used (without a format) to give a title to a PDF file.

Calling `quartz()` sets `.Device` to "quartz" for on-screen devices and to "quartz_off_screen" otherwise.

The font family chosen needs to cover the characters to be used: characters not in the font are rendered as empty oblongs. For non-Western-European languages something other than the default of "Arial" is likely to be needed—one choice for Chinese is "MingLiU".

`quartz.save` is a modified version of `dev.copy2pdf` to copy the plot from the current screen device to a quartz device, by default to a PNG file.

### Conventions

This section describes the implementation of the conventions for graphics devices set out in the ‘R Internals’ manual.

- The default device size is 7 inches square.
- Font sizes are in big points.
- The default font family is Arial.
- Line widths are a multiple of 1/96 inch with no minimum set by R.
- Circle radii are real-valued with no minimum set by R.
- Colours are specified as sRGB.

Note

For a long time the default font family was documented as "Helvetica" after it had been changed to "Arial" to work around a deficiency in macOS 10.4. It may be changed back in future.

A fairly common Mac problem is no text appearing on plots due to corrupted or duplicated fonts on your system. You may be able to confirm this by using another font family, e.g. `family = "serif"`. Open the Font Book application (in Applications) and check the fonts that you are using.

See Also

`quartzFonts`, `Devices`.

`png` for way to access the bitmap types of this device via R’s standard bitmap devices.

Examples

```r
## Not run:
## Only on a Mac,
## put something like this in your .Rprofile to customize the defaults
setHook(packageEvent("grDevices", "onLoad"),
  function(...) grDevices::quartz.options(width = 8, height = 6,
     pointsize = 10))

## End(Not run)
```

---

### quartzFonts

#### Quartz Fonts Setup

**Description**

These functions handle the translation of a device-independent R graphics font family name to a quartz font description.

They are only available on Unix-like systems, i.e., not on Windows, and typically used on the Mac.

**Usage**

```r
quartzFont(family)
quartzFonts(...)
```

**Arguments**

- `family` a character vector containing the four PostScript font names for plain, bold, italic, and bolditalic versions of a font family.
- `...` either character strings naming mappings to display, or new (named) mappings to define.
Details

A quartz device is created with a default font (see the documentation for quartz), but it is also possible to specify a font family when drawing to the device (for example, see the documentation for gpar in the grid package).

The font family sent to the device is a simple string name, which must be mapped to something more specific to quartz fonts. A list of mappings is maintained and can be modified by the user.

The quartzFonts function can be used to list existing mappings and to define new mappings. The quartzFont function can be used to create a new mapping.

Default mappings are provided for three device-independent font family names: "sans" for a sans-serif font, "serif" for a serif font and "mono" for a monospaced font.

See Also

quartz for the default Mac graphics device.

Examples

if(.Platform$OS.type == "unix") { # includes Mac

  utils::str( quartzFonts() ) # a list(serif = .., sans = .., mono = ..)
  quartzFonts("mono") # the list(mono = ..) sublist of quartzFonts()

  ## Not run:
  ## for East Asian locales you can use something like
  quartzFonts(sans = quartzFont(rep("AppleGothic", 4)),
              serif = quartzFont(rep("AppleMyungjp", 4)))
  ## since the default fonts may well not have the glyphs needed

  ## End(Not run)
}

recordGraphics

Record Graphics Operations

Description

Records arbitrary code on the graphics engine display list. Useful for encapsulating calculations with graphical output that depends on the calculations. Intended only for expert use.

Usage

recordGraphics(expr, list, env)

Arguments

expr object of mode expression or call or an unevaluated expression.
list a list defining the environment in which expr is to be evaluated.
env an environment specifying where R looks for objects not found in list.
Details

The code in `expr` is evaluated in an environment constructed from `list`, with `env` as the parent of that environment.

All three arguments are saved on the graphics engine display list so that on a device resize or copying between devices, the original evaluation environment can be recreated and the code can be re-evaluated to reproduce the graphical output.

Value

The value from evaluating `expr`.

Warning

This function is not intended for general use. Incorrect or improper use of this function could lead to unintended and/or undesirable results.

An example of acceptable use is querying the current state of a graphics device or graphics system setting and then calling a graphics function.

An example of improper use would be calling the `assign` function to performing assignments in the global environment.

See Also

eval

Examples

```r
require(graphics)

plot(1:10)
# This rectangle remains 1 inch wide when the device is resized
recordGraphics(
  
  rect(4, 2,
        4 + diff(par("usr"))[1:2])/par("pin")[1], 3)
  
),
list(),
getNamespace("graphics"))
```

---

**recordPlot**

**Record and Replay Plots**

**Description**

Functions to save the current plot in an **R** variable, and to replay it.

**Usage**

```r
recordPlot(load=NULL, attach=NULL)
replayPlot(x, reloadPkgs=FALSE)
```
**Arguments**

- **load**: If not `NULL`, a character vector of package names, which are saved as part of the recorded plot.
- **attach**: If not `NULL`, a character vector of package names, which are saved as part of the recorded plot.
- **x**: A saved plot.
- **reloadPkgs**: A logical indicating whether to reload and/or reattach any packages that were saved as part of the recorded plot.

**Details**

These functions record and replay the displaylist of the current graphics device. The returned object is of class "recordedplot", and `replayPlot` acts as a `print` method for that class.

The returned object is stored as a pairlist, but the usual methods for examining R objects such as `deparse` and `str` are liable to mislead.

**Value**

- `recordPlot` returns an object of class “recordedplot”.
- `replayPlot` has no return value.

**Warning**

The format of recorded plots may change between R versions, so recorded plots should not be used as a permanent storage format for R plots.

As of R 3.3.0, it is possible (again) to replay a plot from another R session using, for example, `saveRDS` and `readRDS`. It is even possible to replay a plot from another R version, however, this will produce warnings, may produce errors, or something worse.

**Note**

Replay of a recorded plot may not produce the correct result (or may just fail) if the display list contains a call to `recordGraphics` which in turn contains an expression that calls code from a non-base package other than `graphics` or `grid`. The most well-known example of this is a plot drawn with the package `ggplot2`. One solution is to load the relevant package(s) before replaying the recorded plot. The `load` and `attach` arguments to `recordPlot` can be used to automate this - any packages named in `load` will be reloaded, via `loadNamespace`, and any packages named in `attach` will be reattached, via `library`, as long as `reloadPkgs` is `TRUE` in the call to `replayPlot`. This is only relevant when attempting to replay in one R session a plot that was recorded in a different R session.

**See Also**

The displaylist can be turned on and off using `dev.control`. Initially recording is on for screen devices, and off for print devices.
Description

This function creates colors corresponding to the given intensities (between 0 and max) of the red, green and blue primaries. The colour specification refers to the standard sRGB colorspace (IEC standard 61966).

An alpha transparency value can also be specified (as an opacity, so 0 means fully transparent and max means opaque). If alpha is not specified, an opaque colour is generated.

The names argument may be used to provide names for the colors.

The values returned by these functions can be used with a col= specification in graphics functions or in par.

Usage

rgb(red, green, blue, alpha, names = NULL, maxColorValue = 1)

Arguments

red, blue, green, alpha

numeric vectors with values in [0, M] where M is maxColorValue. When this is 255, the red, blue, green, and alpha values are coerced to integers in 0:255 and the result is computed most efficiently.

names

character vector. The names for the resulting vector.

maxColorValue

number giving the maximum of the color values range, see above.

Details

The colors may be specified by passing a matrix or data frame as argument red, and leaving blue and green missing. In this case the first three columns of red are taken to be the red, green and blue values.

Semi-transparent colors (0 < alpha < 1) are supported only on some devices: at the time of writing on the pdf, windows, quartz and X11(type = "cairo") devices and associated bitmap devices (jpeg, png, bmp, tiff and bitmap). They are supported by several third-party devices such as those in packages Cairo, cairoDevice and JavaGD. Only some of these devices support semi-transparent backgrounds.

Most other graphics devices plot semi-transparent colors as fully transparent, usually with a warning when first encountered.

NA values are not allowed for any of red, blue, green or alpha.

Value

A character vector with elements of 7 or 9 characters, "#" followed by the red, blue, green and optionally alpha values in hexadecimal (after rescaling to 0...255). The optional alpha values range from 0 (fully transparent) to 255 (opaque).

R does not use 'premultiplied alpha'.

See Also
col2rgb for translating R colors to RGB vectors; rainbow, hsv, hcl, gray.

Examples

rgb(0, 1, 0)
rgb((0:15)/15, green = 0, blue = 0, names = paste("red", 0:15, sep = "."))
rgb(0, 0:12, 0, max = 255) # integer input
ramp <- colorRamp(c("red", "white"))
rgb( ramp(seq(0, 1, length = 5)), max = 255)

Description

col2rgb transforms colors from RGB space (red/green/blue) into HSV space (hue/saturation/value).

Usage

col2rgb(r, g = NULL, b = NULL, maxColorValue = 255)

Arguments

r vector of ‘red’ values in [0, M], (M =maxColorValue) or 3-row rgb matrix.
g vector of ‘green’ values, or NULL when r is a matrix.
b vector of ‘blue’ values, or NULL when r is a matrix.
maxColorValue number giving the maximum of the RGB color values range. The default 255

corresponds to the typical 0:255 RGB coding as in col2rgb().

Details

Value (brightness) gives the amount of light in the color.
Hue describes the dominant wavelength.
Saturation is the amount of Hue mixed into the color.

An HSV colorspace is relative to an RGB colorspace, which in R is sRGB, which has an implicit
gamma correction.

Value

A matrix with a column for each color. The three rows of the matrix indicate hue, saturation
and value and are named "h", "s", and "v" accordingly.

Author(s)

R interface by Wolfram Fischer <wolfram@fischer-zim.ch>
C code mainly by Nicholas Lewin-Koh <nikko@hailmail.net>.
rgb2hsv

See Also
hsv, col2rgb, rgb.

Examples

```r
## These (saturated, bright ones) only differ by hue
(rc <- col2rgb(c("red", "yellow", "green", "cyan", "blue", "magenta")))
(hc <- rgb2hsv(rc))
6 * hc["h",] # the hues are equispaced

(rgb3 <- floor(256 * matrix(stats::runif(3*12), 3, 12)))
(hsv3 <- rgb2hsv(rgb3))

## Consistency:
stopifnot(rgb3 == col2rgb(hsv(h = hsv3[1,], s = hsv3[2,], v = hsv3[3,]),
                        all.equal(hsv3, rgb2hsv(rgb3/255, maxColorValue = 1))))

## A (simplified) pure R version -- originally by Wolfram Fischer --
## showing the exact algorithm:
rgb2hsvR <- function(rgb, gamma = 1, maxColorValue = 255)
{
  if(!is.numeric(rgb)) stop("rgb matrix must be numeric")
  d <- dim(rgb)
  if(d[1] != 3) stop("rgb matrix must have 3 rows")
  n <- d[2]
  if(n == 0) return(cbind(c(h = 1, s = 1, v = 1))[,0])
  rgb <- rgb/maxColorValue
  if(gamma != 1) rgb <- rgb ^ (1/gamma)

  ## get the max and min
  v <- apply(rgb, 2, max)
  s <- apply(rgb, 2, min)
  D <- v - s # range

  ## set hue to zero for undefined values (gray has no hue)
  h <- numeric(n)
  notgray <- (s != v)

  ## blue hue
  idx <- (v == rgb[3,] & notgray)
  if(any(idx))
    h[idx] <- 2/3 + 1/6 * (rgb[1,idx] - rgb[2,idx]) / D[idx]

  ## green hue
  idx <- (v == rgb[2,] & notgray)
  if(any(idx))
    h[idx] <- 1/3 + 1/6 * (rgb[3,idx] - rgb[1,idx]) / D[idx]

  ## red hue
  idx <- (v == rgb[1,] & notgray)
  if(any(idx))

  ## correct for negative red
  idx <- (h < 0)
  h[idx] <- 1-h[idx]

  ## set the saturation
```
\[
\begin{align*}
&\text{s[!notgray] <- 0;} \\
&\text{s[notgray] <- 1 - s[notgray] / v[notgray]} \\
&\text{rbind( h = h, s = s, v = v )}
\end{align*}
\]

## confirm the equivalence:
all.equal(rgb2hsv (rgb3),
          rgb2hsvR(rgb3), tolerance = 1e-14) # TRUE

---

**savePlot**

### Save Cairo X11 Plot to File

**Description**

Save the current page of a cairo **X11**() device to a file.

**Usage**

```r
savePlot(filename = paste0("Rplot.", type),
         type = c("png", "jpeg", "tiff", "bmp"),
         device = dev.cur())
```

**Arguments**

- `filename` : filename to save to.
- `type` : file type.
- `device` : the device to save from.

**Details**

Only cairo-based X11 devices are supported.

This works by copying the image surface to a file. For PNG will always be a 24-bit per pixel PNG `DirectClass` file, for JPEG the quality is 75% and for TIFF there is no compression.

For devices with buffering this copies the buffer's image surface, so works even if `dev.hold` has been called.

The plot is saved after rendering onto the canvas (default opaque white), so for the default `bg = "transparent"` the effective background colour is the canvas colour.

**Value**

Invisible NULL.

**Note**

There is a similar function of the same name but more types for windows devices on Windows: that has an additional argument `restoreConsole` which is only supported on Windows.

**See Also**

`recordPlot()` which is device independent. Further, **X11**, `dev.copy`, `dev.print`
trans3d

3D to 2D Transformation for Perspective Plots

Description

Projection of 3-dimensional to 2-dimensional points using a 4x4 viewing transformation matrix. Mainly for adding to perspective plots such as \texttt{persp}.

Usage

\texttt{trans3d(x, y, z, pmat)}

Arguments

\texttt{x, y, z} numeric vectors of equal length, specifying points in 3D space.

\texttt{pmat} a $4 \times 4$ viewing transformation matrix, suitable for projecting the 3D coordinates $(x, y, z)$ into the 2D plane using homogeneous 4D coordinates $(x, y, z, t)$; such matrices are returned by \texttt{persp()}.

Value

a list with two components

\texttt{x, y} the projected 2d coordinates of the 3d input $(x, y, z)$.

\texttt{persp}

Examples

\begin{verbatim}
## See help(persp) (after attaching the 'graphics' package)
## -----------
\end{verbatim}

Type1Font

Type 1 and CID Fonts

Description

These functions are used to define the translation of a \texttt{R} graphics font family name to a Type 1 or CID font descriptions, used by both the \texttt{postscript} and \texttt{pdf} graphics devices.

Usage

\texttt{Type1Font(family, metrics, encoding = "default")}

\texttt{CIDFont(family, cmap, cmapEncoding, pdfresource = ")")}

\begin{verbatim}
Type1Font

Type 1 and CID Fonts

Description

These functions are used to define the translation of a \texttt{R} graphics font family name to a Type 1 or CID font descriptions, used by both the \texttt{postscript} and \texttt{pdf} graphics devices.

Usage

\texttt{Type1Font(family, metrics, encoding = "default")}

\texttt{CIDFont(family, cmap, cmapEncoding, pdfresource = ")")}
\end{verbatim}
Arguments

family a character string giving the name to be used internally for a Type 1 or CID-keyed font family. This needs to uniquely identify each family, so if you modify a family which is in use (see `postscriptFonts`) you need to change the family name.

metrics a character vector of four or five strings giving paths to the afm (Adobe Font Metric) files for the font.

cmap the name of a CMap file for a CID-keyed font.

cmapEncoding The name of a character encoding to be used with the named CMap file: strings will be translated to this encoding when written to the file.

encoding for Type1Font, the name of an encoding file. Defaults to "default", which maps on Unix-alikes to "ISO88591.ENC" and on Windows to "WinAnsi.ENC". Otherwise, a file name in the ‘enc’ directory of the `grDevices` package, which is used if the path does not contain a path separator. An extension ".enc" can be omitted.

pdfresource A chunk of PDF code; only required for using a CID-keyed font on `pdf`; users should not be expected to provide this.

Details

For Type1Fonts, if four ‘.afm’ files are supplied the fifth is taken to be "Symbol.afm". Relative paths are taken relative to the directory `R_HOME/library/grDevices/afm`. The fifth (symbol) font must be in AdobeSym encoding. However, the glyphs in the first four fonts are referenced by name and any encoding given within the ‘.afm’ files is not used.

The ‘.afm’ files may be compressed with (or without) final extension ‘.gz’: the files which ship with R are installed as compressed files with this extension.

Glyphs in CID-keyed fonts are accessed by ID (number) and not by name. The CMap file maps encoded strings (usually in a MBCS) to IDs, so cmap and cmapEncoding specifications must match. There are no real bold or italic versions of CID fonts (bold/italic were very rarely used in traditional East Asian topography), and for the `pdf` device all four font faces will be identical. However, for the `postscript` device, bold and italic (and bold italic) are emulated.

CID-keyed fonts are intended only for use for the glyphs of East Asian languages, which are all monospaced and are all treated as filling the same bounding box. (Thus `plotmath` will work with such characters, but the spacing will be less carefully controlled than with Western glyphs.) The CID-keyed fonts do contain other characters, including a Latin alphabet: non-East-Asian glyphs are regarded as monospaced with half the width of East Asian glyphs. This is often the case, but sometimes Latin glyphs designed for proportional spacing are used (and may look odd). We strongly recommend that CID-keyed fonts are only used for East Asian glyphs.

Value

A list of class "Type1Font" or "CIDFont".

See Also

`postscript`, `pdf`, `postscriptFonts`, and `pdfFonts`. 
Examples

## This duplicates "ComputerModernItalic".
CMitalic <- Type1Font("ComputerModern2",
c("CM_regular_10.afm", "CM_boldx_10.afm",
"cmti10.afm", "cmbxti10.afm",
"CM_symbol_10.afm"),
encoding = "TeXtext.enc")

## Not run:
## This could be used by
postscript(family = CMitalic)
## or
postscriptFonts(CMitalic = CMitalic)  # once in a session
postscript(family = "CMitalic", encoding = "TeXtext.enc")

## End(Not run)

---

windows Windows Graphics Devices

Description

Available only on Windows. A graphics device is opened. For windows, win.graph, x11 and X11 this is a window on the current Windows display: the multiple names are for compatibility with other systems. win.metafile prints to a file and win.print to the Windows print system.

Usage

windows(width, height, pointsize, record, rescale, xpinch, ypinch,
bg, canvas, gamma, xpos, ypos, buffered, title,
restoreConsole, clickToConfirm, fillOddEven,
family, antialias)

win.graph(width, height, pointsize)

win.metafile(filename = "", width = 7, height = 7, pointsize = 12,
family, restoreConsole = TRUE)

win.print(width = 7, height = 7, pointsize = 12, printer = "",
family, antialias, restoreConsole = TRUE)

Arguments

width, height the (nominal) width and height of the canvas of the plotting window in inches. Default 7.

pointsize the default pointsize of plotted text, interpreted as big points (1/72 inch). Values are rounded to the nearest integer: values less than or equal to zero are reset to 12, the default.

record logical: sets the initial state of the flag for recording plots. Default FALSE.

rescale character, one of c("R","fit","fixed"). Controls the action for resizing of the device. Default "R". See the ‘Resizing options’ section.
windows

xpinch, ypinch double. Pixels per inch, horizontally and vertically. Default NA_real_, which means to take the value from Windows.

bg color. The initial background color. Default "transparent".

canvas color. The color of the canvas which is visible when the background color is transparent. Should be a solid color (and any alpha value will be ignored). Default "white".

gamma gamma correction fudge factor. Colours in R are sRGB; if your monitor does not conform to sRGB, you might be able to improve things by tweaking this parameter to apply additional gamma correction to the RGB channels. By default 1 (no additional gamma correction).

xpos, ypos integer. Position of the top left of the window, in pixels. Negative values are taken from the opposite edge of the monitor. Missing values (the default) mean take the default from the ‘Rconsole’ file, which in turn defaults to xpos = -25, ypos = 0: this puts the right edge of the window 25 pixels from the right edge of the monitor.

buffered logical. Should the screen output be double-buffered? Default TRUE.

title character string, up to 100 bytes. With the default "", a suitable title is created internally. A C-style format for an integer will be substituted by the device number.

filename the name of the output file: it will be an enhanced Windows metafile, usually given extension ‘.emf’ or ‘.wmf’. Up to 511 characters are allowed. The page number is substituted if an integer format is included in the character string (see postscript for further details) and tilde-expansion (see path.expand) is performed. (The result must be less than 600 characters long.) The default, "", means the clipboard.

printer The name of a printer as known to Windows. The default causes a dialog box to come up for the user to choose a printer.

restoreConsole logical: see the ‘Details’ below. Defaults to FALSE for screen devices.

clickToConfirm logical: if true confirmation of a new frame will be by clicking on the device rather than answering a problem in the console. Default TRUE.

fillOddEven logical controlling the polygon fill mode: see polygon for details. Default TRUE.

family A length-one character vector specifying the default font family. See section ‘Fonts’.

antialias A length-one character vector, requesting control over font antialiasing. This is partially matched to "default", "none", "cleartype" or "gray". See the ‘Fonts’ section.

Details

All these devices are implemented as variants of the same device.

All arguments of windows have defaults set by windows.options: the defaults given in the arguments section are the defaults for the defaults. These defaults also apply to the internal values of gamma, xpinch, ypinch, buffered, restoreConsole and antialias for win.graph, x11 and X11.

The size of a window is computed from information provided about the display: it depends on the system being configured accurately. By default a screen device asks Windows for the number of pixels per inch. This can be overridden (it is often wrong) by specifying xpinch and ypinch, most conveniently via windows.options. For example, a 13.3 inch 1280x800 screen (a typical laptop display) was reported as 96 dpi even though it is physically about 114 dpi.
The different colours need to be distinguished carefully. Areas outside the device region are coloured in the Windows application background colour. The device region is coloured in the canvas colour. This is over-painted by the background colour of a plot when a new page is called for, but that background colour can be transparent (and is by default). One difference between setting the canvas colour and the background colour is that when a plot is saved the background colour is copied but the canvas colour is not. The argument bg sets the initial value of par("bg") in base graphics and gpar("fill") in grid graphics.

Recorded plot histories are of class "SavedPlots". They have a print method, and a subset method. As the individual plots are of class "recordedplot" they can be replayed by printing them: see recordPlot. The active plot history is stored in variable .SavedPlots in the workspace.

When a screen device is double-buffered (the default) the screen is updated 100ms after last plotting call or every 500ms during continuous plotting. These times can be altered by setting options("windowsTimeout") to a vector of two integers before opening the device.

Line widths as controlled by par(lwd =) are in multiples of 1/96inch. Multiples less than 1 are allowed, down to one pixel width.

For win.metafile only one plot is allowed per file, and Windows seems to disallow reusing the file. So the only way to allow multiple plots is to use a parametrized filename as in the example. If the filename is omitted (or specified as ""), the output is copied to the clipboard when the device is closed.

The restoreConsole argument is a temporary fix for a problem in the current implementation of several Windows graphics devices, and is likely to be removed in an upcoming release. If set to FALSE, the console will not receive the focus after the new device is opened.

There is support for semi-transparent colours of lines, fills and text on the screen devices. These work for saving (from the 'File' menu) to PDF, PNG, BMP, JPEG and TIFF, but will be ignored if saving to Metafile and PostScript. Limitations in the underlying Windows API mean that a semi-transparent object must be contained strictly within the device region (allowing for line widths and joins).

**Value**

A plot device is opened: nothing is returned to the R interpreter.

**Resizing options**

If a screen device is re-sized, the default behaviour ("R") is to redraw the plot(s) as if the new size had been specified originally. Using "fit" will rescale the existing plot(s) to fit the new device region, preserving the aspect ratio. Using "fixed" will leave the plot size unchanged, adding scrollbars if part of the plot is obscured.

A graphics window will never be created at more than 85% of the screen width or height, but can be resized to a larger size. For the first two rescale options the width and height are rescaled proportionally if necessary, and if rescale = "fit" the plot(s) are rescaled accordingly. If rescale = "fixed" the initially displayed portion is selected within these constraints, separately for width and height. In MDI mode, the limit is 85% of the MDI client region.

Using strwidth or strheight after a window has been rescaled (when using "fit") gives dimensions in the original units, but only approximately as they are derived from the metrics of the rescaled fonts (which are in integer sizes)

The displayed region may be bigger than the 'paper' size, and area(s) outside the 'paper' are coloured in the Windows application background colour. Graphics parameters such as "din" refer to the scaled plot if rescaling is in effect.
Fonts

The fonts used for text drawn in a Windows device may be controlled in two ways. The file \texttt{R_HOME/etc/Rdevga} can be used to specify mappings for \texttt{par(font =)} (or the \texttt{grid} equivalent). Alternatively, a font family can be specified by a non-empty \texttt{family} argument (or by e.g. \texttt{par(family =)} in the graphics package) and this will be used for fonts 1:4 via the Windows font database (see \texttt{windowsFonts}).

How the fonts look depends on the antialiasing settings, both through the \texttt{antialias} argument and the machine settings. These are hints to Windows GDI that may not be able to be followed, but \texttt{antialias = "none"} should ensure that no antialiasing is used. For a screen device the default depends on the machine settings: it will be "cleartype" if that has been enabled. Note that the greyscale antialiasing that is used only for small fonts (below about 9 pixels, around 7 points on a typical display).

When accessing a system through Remote Desktop, both the Remote Desktop settings \texttt{and} the user’s local account settings are relevant to whether antialiasing is used.

Some fonts are intended only to be used with ClearType antialiasing, for example the Meiryo Japanese font.

Conventions

This section describes the implementation of the conventions for graphics devices set out in the ‘R Internals’ manual.

- The default device size is 7 inches square, although this is often incorrectly implemented by Windows: see ‘Details’.
- Font sizes are in big points.
- The default font family is Arial.
- Line widths are as a multiple of 1/96 inch, with a minimum of one pixel.
- The minimum radius of a circle is 1 pixel.
- \texttt{pch = "."} with \texttt{cex = 1} corresponds to a rectangle of sides the larger of one pixel and 0.01 inch.
- Colours are interpreted via the unprofiled colour mapping of the graphics card – this is assumed to conform to sRGB.

Note

\texttt{x11()}, \texttt{X11()} and \texttt{win.graph()} are simple wrappers calling \texttt{windows()}, and mainly exist for compatibility reasons.

Further, \texttt{x11()} and \texttt{X11()} have their own help page for Unix-alikes (where they also have more arguments).

Examples

```r
## Not run: ## A series of plots written to a sequence of metafiles
if(.Platform$OS.type == "windows")
  win.metafile("Rplot%02d.wmf", pointsize = 10)
```

## End(Not run)
windows.options  

Auxiliary Function to Set/View Defaults for Arguments of windows()

Description

The auxiliary function `windows.options` can be used to set or view (if called without arguments) the default values for the arguments of `windows`.

`windows.options` needs to be called before calling `windows`, and the default values it sets can be overridden by supplying arguments to `windows`.

Usage

`windows.options(..., reset = FALSE)`

Arguments

- `...`: arguments `width`, `height`, `pointsize`, `record`, `rescale`, `xpinch`, `ypinch`, `bg`, `canvas`, `gamma`, `xpos`, `ypos`, `buffered`, `restoreConsole`, `clickToConfirm`, `title`, `fillOddEven` and `antialias` can be supplied.
- `reset`: logical: should the defaults be reset to their ‘factory-fresh’ values?

Details

If both `reset = TRUE` and `...` are supplied the defaults are first reset to the ‘factory-fresh’ values and then the new values are applied.

Option `antialias` applies to screen devices (`windows`, `win.graph`, `X11` and `x11`). There is a separate option, `bitmap.aa.win`, for bitmap devices with `type = "windows"`.

Value

A named list of all the defaults. If any arguments are supplied the returned values are the old values and the result has the visibility flag turned off.

See Also

`windows`, `ps.options`.

Examples

```r
## Not run:
## put something like this in your .Rprofile to customize the defaults
setHook(packageEvent("grDevices", "onLoad"),
    function(...)
        grDevices::windows.options(width = 8, height = 6,
            xpos = 0, pointsize = 10,
            bitmap.aa.win = "cleartype")
        )

## End(Not run)
```
Description

These functions handle the translation of a device-independent R graphics font family name to a windows font description and are available only on Windows.

Usage

```r
windowsFont(family)
windowsFonts(...)
```

Arguments

- `family` a character vector containing the font family name ("TT" as the first two characters indicates a TrueType font).
- `...` either character strings naming mappings to display, or new (named) mappings to define.

Details

A windows device is created with a default font (see the documentation for `windows`), but it is also possible to specify a font family when drawing to the device (for example, see the documentation for "family" in `par` and for "fontfamily" in `gpar` in the `grid` package).

The font family sent to the device is a simple string name, which must be mapped to something more specific to windows fonts. A list of mappings is maintained and can be modified by the user.

The `windowsFonts` function can be used to list existing mappings and to define new mappings. The `windowsFont` function can be used to create a new mapping.

Default mappings are provided for three device-independent font family names: "sans" for a sans-serif font, "serif" for a serif font and "mono" for a monospaced font.

These mappings will only be used if the current font face is 1 (plain), 2 (bold), 3 (italic), or 4 (bolditalic).

See Also

`windows`

Examples

```r
if(.Platform$OS.type == "windows") withAutoprint({
  windowsFonts()
  windowsFonts("mono")
})
## Not run: ## set up for Japanese: needs the fonts installed
windows() # make sure we have the right device type (available on Windows only)
Sys.setlocale("LC_ALL", "ja")
windowsFonts(JP1 = windowsFont("MS Mincho"),
            JP2 = windowsFont("MS Gothic"),
            JP3 = windowsFont("Arial Unicode MS"))
```
plot(1:10)  
text(5, 2, \"\\u{4E10}\\u{4E00}\\u{4E01}\", family = "JP1")  
text(7, 2, \"\\u{4E10}\\u{4E00}\\u{4E01}\", family = "JP1", font = 2)  
text(5, 1.5, \"\\u{4E10}\\u{4E00}\\u{4E01}\", family = "JP2")  
text(9, 2, \"\\u{5100}\", family = "JP3")

## End(Not run)

---

xii

X Window System Graphics (X11)

Description

**on Windows**, the `X11()` and `x11()` functions are simple wrappers to `windows()` for historical compatibility convenience: Calling `x11()` or `X11()` would work in most cases to open an interactive graphics device.

In R versions before 3.6.0, the Windows version had a shorter list of formal arguments. Consequently, calls to `X11(*)` with arguments should name them for back compatibility. Almost all information below does not apply on Windows.

**on Unix-alikes** `X11` starts a graphics device driver for the X Window System (version 11). This can only be done on machines/accounts that have access to an X server.

`x11` is recognized as a synonym for `X11`.

The R function is a wrapper for two devices, one based on Xlib ([https://en.wikipedia.org/wiki/Xlib](https://en.wikipedia.org/wiki/Xlib)) and one using cairographics ([https://www.cairographics.org](https://www.cairographics.org)).

Usage

```r
X11(display = ", width, height, pointsize, gamma, bg, canvas, fonts, family, xpos, ypos, title, type, antialias, symbolfamily)
X11.options(..., reset = FALSE)
```

Arguments

- **display**
  - the display on which the graphics window will appear. The default is to use the value in the user’s environment variable `DISPLAY`. This is ignored (with a warning) if an X11 device is already open on another display.

- **width, height**
  - the width and height of the plotting window, in inches. If NA, taken from the resources and if not specified there defaults to 7 inches. See also ‘Resources’.

- **pointsize**
  - the default pointsize to be used. Defaults to 12.

- **gamma**
  - gamma correction fudge factor. Colours in R are sRGB; if your monitor does not conform to sRGB, you might be able to improve things by tweaking this parameter to apply additional gamma correction to the RGB channels. By default 1 (no additional gamma correction).

- **bg**
  - colour, the initial background colour. Default "transparent".

- **canvas**
  - colour. The colour of the canvas, which is visible only when the background colour is transparent. Should be an opaque colour (and any alpha value will be ignored). Default "white".
fonts
for type = "Xlib" only: X11 font description strings into which weight, slant and size will be substituted. There are two, the first for fonts 1 to 4 and the second for font 5, the symbol font. See section ‘Fonts’.

family
The default family: a length-one character string. This is primarily intended for cairo-based devices, but for type = "Xlib", the X11Fonts() database is used to map family names to fonts (and this argument takes precedence over that one).

xpos, ypos
integer: initial position of the top left corner of the window, in pixels. Negative values are from the opposite corner, e.g. xpos = -100 says the top right corner should be 100 pixels from the right edge of the screen. If NA (the default), successive devices are cascaded in 20 pixel steps from the top left. See also ‘Resources’.

title
character string, up to 100 bytes. With the default, "", a suitable title is created internally. A C-style format for an integer will be substituted by the device number (see the file argument to postscript for further details). How non-ASCII titles are handled is implementation-dependent.

type
character string, one of "Xlib", "cairo", "nbcairo" or "dbcairo". Only the first will be available if the system was compiled without support for cairo-graphics. The default is "cairo" where available except on macOS, otherwise "Xlib".

antialias
for cairo types, the type of anti-aliasing (if any) to be used. One of c("default", "none", "gray", "subpixel").

symbolfamily
for cairo-based devices only: a length-one character string that specifies the font family to be used as the "symbol" font (e.g., for plotmath output). The default value is "default", which means that R will choose a default "symbol" font based on the graphics device capabilities.

reset
logical: should the defaults be reset to their defaults?

... Any of the arguments to X11, plus colortype and maxcubesize (see section ‘Colour Rendering’).

Details

The defaults for all of the arguments of X11 are set by X11.options: the ‘Arguments’ section gives the ‘factory-fresh’ defaults.

The initial size and position are only hints, and may not be acted on by the window manager. Also, some systems (especially laptops) are set up to appear to have a screen of a different size to the physical screen.

Option type selects between two separate devices: R can be built with support for neither, type = "Xlib" or both. Where both are available, types "cairo", "nbcairo" and "dbcairo" offer

- antialiasing of text and lines.
- translucent colours.
- scalable text, including to sizes like 4.5 pt.
- full support for UTF-8, so on systems with suitable fonts you can plot in many languages on a single figure (and this will work even in non-UTF-8 locales). The output should be locale-independent.

There are three variants of the cairo-based device. type = "nbcairo" has no buffering. type = "cairo" has some buffering, and supports dev.hold and dev.flush. type = "dbcairo" buffers output and updates the screen about every 100ms (by default). The refresh interval can be set (in
units of seconds) by e.g. `options(X11updates = 0.25)`: the value is consulted when a device is opened. Updates are only looked for every 50ms (at most), and during heavy graphics computations only every 500ms.

Which version will be fastest depends on the X11 connection and the type of plotting. You will probably want to use a buffered type unless backing store is in use on the X server (which for example it always is on macOS displays), as otherwise repainting when the window is exposed will be slow. On slow connections type = "dcairo" will probably give the best performance.

Because of known problems with font selection on macOS without Pango (for example, the CRAN distribution), type = "cairo" is not the default there. These problems have included mixing up bold and italic (since worked around), selecting incorrect glyphs and ugly or missing symbol glyphs.

All devices which use an X11 server (including the type = "Xlib" versions of bitmap devices such as `png`) share internal structures, which means that they must use the same display and visual. If you want to change display, first close all such devices.

The cursor shown indicates the state of the device. If quiescent the cursor is an arrow: when the locator is in use it is a crosshair cursor, and when plotting computations are in progress (and this can be detected) it is a watch cursor. (The exact cursors displayed will depend on the window manager in use.)

**X11 Fonts**

This section applies only to type = "Xlib".

An initial/default font family for the device can be specified via the `fonts` argument, but if a device-independent R graphics font family is specified (e.g., via `par(family =)` in the graphics package), the X11 device makes use of the X11 font database (see X11Fonts) to convert the R graphics font family to an X11-specific font family description. If `family` is supplied as an argument, the X11 font database is used to convert that, but otherwise the argument `fonts` (with default given by `X11.options`) is used.

X11 chooses fonts by matching to a pattern, and it is quite possible that it will choose a font in the wrong encoding or which does not contain glyphs for your language (particularly common in `iso10646-1` fonts).

The `fonts` argument is a two-element character vector, and the first element will be crucial in successfully using non-Western-European fonts. Settings that have proved useful include

"*-mincho-%s-%s-****d-************" for CJK languages and
"-cronyx-helvetica-%s-%s-****d-************" for Russian.

For UTF-8 locales, the `XLC_LOCALE` databases provide mappings between character encodings, and you may need to add an entry for your locale (e.g., Fedora Core 3 lacked one for `ru_RU.utf8`).

**Cairo Fonts**

The cairographics-based devices work directly with font family names such as "Helvetica" which can be selected initially by the family argument and subsequently by `par` or `gpar`. There are mappings for the three device-independent font families, "sans" for a sans-serif font (to "Helvetica"), "serif" for a serif font (to "Times") and "mono" for a monospaced font (to "Courier").

The font selection is handled by Pango (usually via `fontconfig`) or `fontconfig` (on macOS and perhaps elsewhere). The results depend on the fonts installed on the system running R – setting the environment variable `FC_DEBUG` to 1 normally allows some tracing of the selection process.

This works best when high-quality scalable fonts are installed, usually in Type 1 or TrueType formats: see the ‘R Installation and Administration’ manual for advice on how to obtain and install such fonts. At present the best rendering (including using kerning) will be achieved with TrueType
fonts: see https://www.freedesktop.org/software/fontconfig/fontconfig-user.html for ways to set up your system to prefer them. The default family ("Helvetica") is likely not to use kerning: alternatives which should if you have them installed are "Arial", "DejaVu Sans" and "Liberation Sans" (and perhaps "FreeSans"). For those who prefer fonts with serifs, try "Times New Roman", "DejaVu Serif" and "Liberation Serif". To match LaTeX text, use something like "CM Roman".

Fedora systems from version 31 on do not like the default "symbol" font family for rendering symbols (e.g., `plotmath`). For those systems, users should specify a different font via `symbolfamily`. The default can also be changed via `X11.options`.

Problems with incorrect rendering of symbols (e.g., of `quote(pi)` and `expression(10^degree)`) have been seen on Linux systems which have the Wine symbol font installed – fontconfig then prefers this and misinterprets its encoding. Adding the following lines to `~/.fonts.conf` or `/etc/fonts/local.conf` may circumvent this problem by preferring the URW Type 1 symbol font.

```xml
<fontconfig>
<match target="pattern">
  <test name="family"><string>Symbols</string></test>
  <edit name="family" mode="prepend" binding="same">
    <string>Standard Symbols L</string>
  </edit>
</match>
</fontconfig>
```

A test for this is to run at the command line `fc-match Symbols`. If that shows `symbol.ttf` that may be the Wine symbol font – use `locate symbol.ttf` to see if it is found from a directory with 'wine' in the name.

**Resources**

The standard X11 resource `geometry` can be used to specify the window position and/or size, but will be overridden by values specified as arguments or non-NA defaults set in `X11.options`. The class looked for is `R_x11`. Note that the resource specifies the width and height in pixels and not in inches. See for example 'man X' (or https://www.x.org/releases/current/). An example line in `~/.Xresources` might be

```sh
R_x11*geometry: 900x900-0+0
```

which specifies a 900 x 900 pixel window at the top right of the screen.

**Colour Rendering**

X11 supports several ‘visual’ types, and nowadays almost all systems support ‘truecolor’ which X11 will use by default. This uses a direct specification of any RGB colour up to the depth supported (usually 8 bits per colour). Other visuals make use of a palette to support fewer colours, only grays or even only black/white. The palette is shared between all X11 clients, so it can be necessary to limit the number of colours used by R.

The default for `type = "Xlib"` is to use the best possible colour model for the visual of the X11 server: these days this will almost always be ‘truecolor’. This can be overridden by the `colortype` argument of `X11.options`. **Note:** All X11 and `type = "Xlib"` `bmp`, `jpeg`, `png` and `tiff` devices share a `colortype` which is set when the first device to be opened. To change the `colortype` you need to close all open such devices, and then use `X11.options(colortype =).`
The colortype types are tried in the order "true", "pseudo", "gray" and "mono" (black or white only). The values "pseudo" and "pseudo.cube" provide two colour strategies for a pseudocolor visual. The first strategy provides on-demand colour allocation which produces exact colours until the colour resources of the display are exhausted (when plotting will fail). The second allocates (if possible) a standard colour cube, and requested colours are approximated by the closest value in the cube.

With colortype equal to "pseudo.cube" or "gray" successively smaller palettes are tried until one is completely allocated. If allocation of the smallest attempt fails the device will revert to "mono". For "gray" the search starts at 256 grays for a display with depth greater than 8, otherwise with half the available colours. For "pseudo.cube" the maximum cube size is set by \f{X11.options(maxcolorsizer =)} and defaults to 256. With that setting the largest cube tried is 4 levels each for RGB, using 64 colours in the palette.

The cairographics-based devices most likely only work (or work correctly) with 'TrueColor' visuals, although in principle this depends on the cairo installation: a warning is given if any other visual is encountered.

type = "Xlib" supports 'TrueColor', 'PseudoColor', 'GrayScale', StaticGray and MonoChrome visuals: 'StaticColor' and 'DirectColor' visuals are handled only in black/white.

Anti-aliasing

Anti-aliasing is only supported for cairographics-based devices, and applies to both graphics and fonts. It is generally preferable for lines and text, but can lead to undesirable effects for fills, e.g. for image plots, and so is never used for fills.

antialias = "default" is in principle platform-dependent, but seems most often equivalent to antialias = "gray".

Conventions

This section describes the implementation of the conventions for graphics devices set out in the ‘R Internals’ manual.

- The default device size is 7 inches square.
- Font sizes are in big points.
- The default font family is Helvetica.
- Line widths in 1/96 inch, minimum one pixel for type = "Xlib", 0.01 otherwise.
- For type = "Xlib" circle radii are in pixels with minimum one.
- Colours are interpreted by the X11 server, which is assumed to conform to sRGB.

Devices, X11Fonts, savePlot.

Examples

```r
## Not run:
if(.Platform$OS.type == "unix") { # Only on unix-alikes, possibly Mac,
  ## put something like this in your .Rprofile to customize the defaults
  setHook(packageEvent("grDevices", "onLoad"),
    function(...) grDevices::X11.options(width = 8, height = 6, xpos = 0,
      pointsize = 10))
}
## End(Not run)
```
Description

These functions handle the translation of a device-independent R graphics font family name to an X11 font description on Unix-alike platforms.

Usage

\begin{verbatim}
X11Font(font)
X11Fonts(...)  
\end{verbatim}

Arguments

- `font`: a character string containing an X11 font description.
- `...`: either character strings naming mappings to display, or new (named) mappings to define.

Details

These functions apply only to an X11 device with type = "Xlib" – X11(type = "cairo") uses a different mechanism to select fonts.

Such a device is created with a default font (see the documentation for X11), but it is also possible to specify a font family when drawing to the device (for example, see the documentation for "family" in par and for "fontfamily" in gpar in the grid package).

The font family sent to the device is a simple string name, which must be mapped to something more specific to X11 fonts. A list of mappings is maintained and can be modified by the user.

The X11Fonts function can be used to list existing mappings and to define new mappings. The X11Font function can be used to create a new mapping.

Default mappings are provided for three device-independent font family names: "sans" for a sans-serif font, "serif" for a serif font and "mono" for a monospaced font. Further mappings are provided for "Helvetica" (the device default), "Times", "CyrHelvetica", "CyrTimes" (versions of these fonts with Cyrillic support, at least on Linux), "Arial" (on some platforms including macOS and Solaris) and "Mincho" (a CJK font).

Note

Available only when capabilities()[["X11"]]] is true.

if(capabilities()["X11"]) withAutoprint(
  X11Fonts()
  X11Fonts("mono")
  utopia <- X11Font("*-utopia-*-*-*-*-*-*-*-*-*-*-*-*")
  X11Fonts(utopia = utopia)
)
## IGNORE_RDIFF_END
```

---

xfig  

**XFig Graphics Device**

Description

*xfig* starts the graphics device driver for producing XFig (version 3.2) graphics.

The auxiliary function *ps.options* can be used to set and view (if called without arguments) default values for the arguments to *xfig* and *postscript*.

Usage

```r
xfig(file = if(onefile) "Rplots.fig" else "Rplot%03d.fig",
     onefile = FALSE, encoding = "none",
     paper = "default", horizontal = TRUE,
     width = 0, height = 0, family = "Helvetica",
     pointsize = 12, bg = "transparent", fg = "black",
     pagecentre = TRUE, defaultfont = FALSE, textspecial = FALSE)
```

Arguments

- **file**: a character string giving the file path. For use with *onefile* = FALSE give a C integer format such as "Rplot%03d.fig" (the default in that case). (See *postscript* for further details.)
- **onefile**: logical: if true allow multiple figures in one file. If false, assume only one page per file and generate a file number containing the page number.
- **encoding**: The encoding in which to write text strings. The default is not to re-encode. This can be any encoding recognized by *iconv*: in a Western UTF-8 locale you probably want to select an 8-bit encoding such as *latin1*, and in an East Asian locale an EUC encoding. If re-encoding fails, the text strings will be written in the current encoding with a warning.
- **paper**: the size of paper region. The choices are "A4", "Letter" and "Legal" (and these can be lowercase). A further choice is "default", which is the default. If this is selected, the papersize is taken from the option "papersize" if that is set to a non-empty value, otherwise "A4".
- **horizontal**: the orientation of the printed image, a logical. Defaults to true, that is landscape orientation.
- **width, height**: the width and height of the graphics region in inches. The default is to use the entire page less a 0.5 inch overall margin in each direction. (See *postscript* for further details.)
family the font family to be used. This must be one of "AvantGarde", "Bookman", "Courier", "Helvetica" (the default), "Helvetica-Narrow", "NewCenturySchoolbook", "Palatino" or "Times". Any other value is replaced by "Helvetica", with a warning.

points the default points size to be used.

bg the initial background color to be used.

fg the initial foreground color to be used.

pagecentre logical: should the device region be centred on the page?

defaultfont logical: should the device use xfig’s default font?

textspecial logical: should the device set the textspecial flag for all text elements. This is useful when generating pstex from xfig figures.

Details

Although xfig can produce multiple plots in one file, the XFig format does not say how to separate or view them. So onefile = FALSE is the default.

The file argument is interpreted as a C integer format as used by sprintf, with integer argument the page number. The default gives files ‘Rplot001.fig’, ‘Rplot999.fig’, ‘Rplot1000.fig’, . . .

Line widths as controlled by par(lwd =) are in multiples of 5/6 inch. Multiples less than 1 are allowed. pch = "." with cex = 1 corresponds to a square of side 1/72 inch.

Windows users can make use of WinFIG (http://www.schmidt-web-berlin.de/WinFIG.htm, shareware), or XFig under Cygwin.

Conventions

This section describes the implementation of the conventions for graphics devices set out in the ‘R Internals’ manual.

• The default device size is the paper size with a 0.25 inch border on all sides.
• Font sizes are in big points.
• The default font family is Helvetica.
• Line widths are integers, multiples of 5/432 inch.
• Circle radii are multiples of 1/1200 inch.
• Colours are interpreted by the viewing/printing application.

Note

Only some line textures (0 <= lty < 4) are used. Eventually this may be partially remedied, but the XFig file format does not allow as general line textures as the R model. Unimplemented line textures are displayed as dash-double-dotted.

There is a limit of 512 colours (plus white and black) per file.

Devices, postscript, ps.options.
Description

`xy.coords` is used by many functions to obtain x and y coordinates for plotting. The use of this common mechanism across all relevant R functions produces a measure of consistency.

Usage

```r
xy.coords(x, y = NULL, xlab = NULL, ylab = NULL, log = NULL,
          recycle = FALSE, setLab = TRUE)
```

Arguments

- `x, y` the x and y coordinates of a set of points. Alternatively, a single argument `x` can be provided.
- `xlab, ylab` names for the x and y variables to be extracted.
- `log` character, "x", "y" or both, as for `plot`. Sets negative values to `NA` and gives a warning.
- `recycle` logical; if TRUE, recycle (`rep`) the shorter of `x` or `y` if their lengths differ.
- `setLab` logical indicating if the resulting `xlab` and `ylab` should be constructed from the "kind" of `(x,y)"; otherwise, the arguments `xlab` and `ylab` are used.

Details

An attempt is made to interpret the arguments `x` and `y` in a way suitable for bivariate plotting (or other bivariate procedures).

If `y` is `NULL` and `x` is a

- `formula`: of the form `yvar ~ xvar`. `xvar` and `yvar` are used as x and y variables.
- `list`: containing components `x` and `y`, these are used to define plotting coordinates.
- `time series`: the x values are taken to be `time(x)` and the y values to be the time series.
- `matrix or data.frame with two or more columns`: the first is assumed to contain the x values and the second the y values. `Note` that is also true if `x` has columns named "x" and "y"; these names will be irrelevant here.

In any other case, the x argument is coerced to a vector and returned as y component where the resulting x is just the index vector 1:n. In this case, the resulting `xlab` component is set to "Index" (if `setLab` is true as by default).

If `x` (after transformation as above) inherits from class "POSIXt" it is coerced to class "POSIXct".

Value

A list with the components

- `x` numeric (i.e., "double") vector of abscissa values.
- `y` numeric vector of the same length as `x`.
- `xlab` character(1) or `NULL`, the 'label' of `x`.
- `ylab` character(1) or `NULL`, the 'label' of `y`. 
### xyTable

**Multiplicities of (x,y) Points, e.g., for a Sunflower Plot**

### Description

Given (x,y) points, determine their multiplicity – checking for equality only up to some (crude kind of) noise. Note that this is special kind of 2D binning.

### Usage

```r
xyTable(x, y = NULL, digits)
```

### Arguments

- **x, y**: numeric vectors of the same length; alternatively other (x, y) argument combinations as allowed by `xy.coords(x,y)`.
- **digits**: integer specifying the significant digits to be used for determining equality of coordinates. These are compared after rounding them via `signif(*,digits)`.

### Value

A list with three components of same length,

- **x**: x coordinates, rounded and sorted.
- **y**: y coordinates, rounded (and sorted within x).
- **number**: multiplicities (positive integers); i.e., `number[i]` is the multiplicity of `(x[i],y[i])`.

### See Also

- `sunflowerplot` which typically uses `xyTable(); signif`.

### Examples

```r
ff <- stats::fft(1:9)
xy.coords(ff)
xy.coords(ff, xlab = "fft")  # labels "Re(ff)", "Im(ff)"

with(cars, xy.coords(dist ~ speed, NULL)$xlab )  # = "speed"

xy.coords(1:3, 1:2, recycle = TRUE)  # otherwise error "lengths differ"
xy.coords(-2:10, log = "y")
  ### xlab: "Index" \ warning: 3 y values <= 0 omitted ..
```
Examples

```r
xyTable(iris[, 3:4], digits = 6)

## Discretized uncorrelated Gaussian:
```
```r
require(stats)
xy <- data.frame(x = round(sort(rnorm(100))), y = rnorm(100))
xyTable(xy, digits = 1)
```

Description

Utility for obtaining consistent x, y and z coordinates and labels for three dimensional (3D) plots.

Usage

```r
xyz.coords(x, y = NULL, z = NULL,
            xlab = NULL, ylab = NULL, zlab = NULL,
            log = NULL, recycle = FALSE, setLab = TRUE)
```

Arguments

- **x, y, z**: the x, y and z coordinates of a set of points. Both y and z can be left at NULL. In this case, an attempt is made to interpret x in a way suitable for plotting. If the argument is a formula `zvar ~ xvar + yvar`, `xvar`, `yvar` and `zvar` are used as x, y and z variables; if the argument is a list containing components `x`, `y` and `z`, these are assumed to define plotting coordinates; if the argument is a matrix or `data.frame` with three or more columns, the first is assumed to contain the x values, the 2nd the y ones, and the 3rd the z ones – independently of any column names that `x` may have. Alternatively two arguments `x` and `y` can be provided (leaving `z` = NULL). One may be real, the other complex; in any other case, the arguments are coerced to vectors and the values plotted against their indices.

- **xlab, ylab, zlab**: names for the x, y and z variables to be extracted.

- **log**: character, "x", "y", "z" or combinations. Sets negative values to `NA` and gives a warning.

- **recycle**: logical; if TRUE, recycle `rep`) the shorter ones of x, y or z if their lengths differ.

- **setLab**: logical indicating if the resulting `xlab` and `ylab` should be constructed from the "kind" of `(x,y)`; otherwise, the arguments `xlab` and `ylab` are used.

Value

A list with the components

- **x**: numeric (i.e., `double`) vector of abscissa values.
- **y**: numeric vector of the same length as x.
- **z**: numeric vector of the same length as x.
xyz.coords

xlab character(1) or NULL, the axis label of x.
ylab character(1) or NULL, the axis label of y.
zlab character(1) or NULL, the axis label of z.

Maintainer: R Core Team <R-core@r-project.org>

References

abline
Add Straight Lines to a Plot

Description
This function adds one or more straight lines through the current plot.

Usage
abline(a = NULL, b = NULL, h = NULL, v = NULL, reg = NULL, coef = NULL, untf = FALSE, ...)
Arguments

\(a\), \(b\)  
the intercept and slope, single values.

\(\text{untf}\)  
logical asking whether to untransform. See ‘Details’.

\(h\)  
the \(y\)-value(s) for horizontal line(s).

\(v\)  
the \(x\)-value(s) for vertical line(s).

\(\text{coef}\)  
a vector of length two giving the intercept and slope.

\(\text{reg}\)  
an object with a \text{coef} method. See ‘Details’.

\(\ldots\)  
\text{graphical parameters} such as \text{col}, \text{1ty} and \text{1wd} (possibly as vectors: see ‘Details’) and \text{xpd} and the line characteristics \text{lend}, \text{ljoin} and \text{lmitre}.

Details

Typical usages are

\[
\begin{align*}
\text{abline}(a, b, \ldots) \\
\text{abline}(h =, \ldots) \\
\text{abline}(v =, \ldots) \\
\text{abline(coef =, \ldots)} \\
\text{abline(reg =, \ldots)}
\end{align*}
\]

The first form specifies the line in intercept/slope form (alternatively \(a\) can be specified on its own and is taken to contain the slope and intercept in vector form).

The \(h=\) and \(v=\) forms draw horizontal and vertical lines at the specified coordinates.

The \text{coef} form specifies the line by a vector containing the slope and intercept.

\text{reg} is a regression object with a \text{coef} method. If this returns a vector of length 1 then the value is taken to be the slope of a line through the origin, otherwise, the first 2 values are taken to be the intercept and slope.

If \(\text{untf}\) is true, and one or both axes are log-transformed, then a curve is drawn corresponding to a line in original coordinates, otherwise a line is drawn in the transformed coordinate system. The \(h\) and \(v\) parameters always refer to original coordinates.

The \text{graphical parameters} \text{col}, \text{1ty} and \text{1wd} can be specified; see \text{par} for details. For the \(h=\) and \(v=\) usages they can be vectors of length greater than one, recycled as necessary.

Specifying an \text{xpd} argument for clipping overrides the global \text{par}(“xpd”) setting used otherwise.

References

See Also

\text{lines} and \text{segments} for connected and arbitrary lines given by their endpoints. \text{par}.
Examples

## Setup up coordinate system (with x == y aspect ratio):
plot(c(-2,3), c(-1,5), type = "n", xlab = "x", ylab = "y", asp = 1)
## the x- and y-axis, and an integer grid
abline(h = 0, v = 0, col = "gray60")
text(1,0, "abline( h = 0 )", col = "gray60", adj = c(0, -.1))
abline(h = -1:5, v = -2:3, col = "lightgray", lty = 3)
abline(a = 1, b = 2, col = 2)
text(1,3, "abline( 1, 2 )", col = 2, adj = c(-.1, -.1))

## Simple Regression Lines:
require(stats)
sale5 <- c(6, 4, 9, 7, 6, 12, 8, 10, 9, 13)
plot(sale5)
abline(lsfit(1:10, sale5))
abline(lsfit(1:10, sale5, intercept = FALSE), col = 4) # less fitting

z <- lm(dist ~ speed, data = cars)
plot(cars)
abline(z) # equivalent to abline(reg = z) or
abline(coef = coef(z))

## trivial intercept model
abline(mC <- lm(dist ~ 1, data = cars)) ## the same as
abline(a = coef(mC), b = 0, col = "blue")

arrows

Add Arrows to a Plot

Description

Draw arrows between pairs of points.

Usage

arrows(x0, y0, x1 = x0, y1 = y0, length = 0.25, angle = 30,
        code = 2, col = par("fg"), lty = par("lty"),
        lwd = par("lwd"), ...)

Arguments

  x0, y0
coordinates of points from which to draw.
  x1, y1
coordinates of points to which to draw. At least one must the supplied
  length
length of the edges of the arrow head (in inches).
  angle
angle from the shaft of the arrow to the edge of the arrow head.
  code
integer code, determining kind of arrows to be drawn.
  col, lty, lwd
  graphical parameters, possible vectors. NA values in col cause the arrow to be omitted.
  ...
  graphical parameters such as xpd and the line characteristics lend, ljoin and lmitre: see par.
assocplot

Details

For each i, an arrow is drawn between the point \((x0[i], y0[i])\) and the point \((x1[i], y1[i])\). The coordinate vectors will be recycled to the length of the longest.

If code = 1 an arrowhead is drawn at \((x0[i], y0[i])\) and if code = 2 an arrowhead is drawn at \((x1[i], y1[i])\). If code = 3 a head is drawn at both ends of the arrow. Unless length = 0, when no head is drawn.

The graphical parameters \(col\), \(lty\) and \(lwd\) can be vectors of length greater than one and will be recycled if necessary.

The direction of a zero-length arrow is indeterminate, and hence so is the direction of the arrowheads. To allow for rounding error, arrowheads are omitted (with a warning) on any arrow of length less than 1/1000 inch.

Note

The first four arguments in the comparable S function are named \(x1, y1, x2, y2\).

References

See Also

segments to draw segments.

Examples

```r
x <- stats::runif(12); y <- stats::rnorm(12)
i <- order(x, y); x <- x[i]; y <- y[i]
plot(x, y, main = "arrows(.) and segments(.)")
## draw arrows from point to point :
s <- seq(length(x)-1) # one shorter than data
arrows(x[s], y[s], x[s+1], y[s+1], col = 1:3)
s <- s[-length(s)]
segments(x[s], y[s], x[s+2], y[s+2], col = "pink")
```

assocplot

Association Plots

Description

Produce a Cohen-Friendly association plot indicating deviations from independence of rows and columns in a 2-dimensional contingency table.

Usage

```r
assocplot(x, col = c("black", "red"), space = 0.3,
main = NULL, xlab = NULL, ylab = NULL)
```
assocplot

Arguments

- **x**: a two-dimensional contingency table in matrix form.
- **col**: a character vector of length two giving the colors used for drawing positive and negative Pearson residuals, respectively.
- **space**: the amount of space (as a fraction of the average rectangle width and height) left between each rectangle.
- **main**: overall title for the plot.
- **xlab**: a label for the x axis. Defaults to the name (if any) of the row dimension in x.
- **ylab**: a label for the y axis. Defaults to the name (if any) of the column dimension in x.

Details

For a two-way contingency table, the signed contribution to Pearson’s $\chi^2$ for cell $i,j$ is $d_{ij} = (f_{ij} - e_{ij})/\sqrt{e_{ij}}$, where $f_{ij}$ and $e_{ij}$ are the observed and expected counts corresponding to the cell. In the Cohen-Friendly association plot, each cell is represented by a rectangle that has (signed) height proportional to $d_{ij}$ and width proportional to $\sqrt{e_{ij}}$, so that the area of the box is proportional to the difference in observed and expected frequencies. The rectangles in each row are positioned relative to a baseline indicating independence ($d_{ij} = 0$). If the observed frequency of a cell is greater than the expected one, the box rises above the baseline and is shaded in the color specified by the first element of **col**, which defaults to black; otherwise, the box falls below the baseline and is shaded in the color specified by the second element of **col**, which defaults to red.

A more flexible and extensible implementation of association plots written in the grid graphics system is provided in the function `assoc` in the contributed package `vcd` (Meyer, Zeileis and Hornik, 2006).

See Also

- `mosaicplot`, `chisq.test`.

Examples

```r
## Aggregate over sex:
x <- marginSums(HairEyeColor, c(1, 2))
x
assocplot(x, main = "Relation between hair and eye color")
```
**Axis**

*Generic Function to Add an Axis to a Plot*

**Description**

Generic function to add a suitable axis to the current plot.

**Usage**

\[
\text{Axis}(x = \text{NULL}, \ at = \text{NULL}, \ldots, \ side, \ labels = \text{NULL})
\]

**Arguments**

- **x**: an object which indicates the range over which an axis should be drawn
- **at**: the points at which tick-marks are to be drawn.
- **side**: an integer specifying which side of the plot the axis is to be drawn on. The axis is placed as follows: 1=below, 2=left, 3=above and 4=right.
- **labels**: this can either be a logical value specifying whether (numerical) annotations are to be made at the tickmarks, or a character or expression vector of labels to be placed at the tickpoints. If this is specified as a character or expression vector, **at** should be supplied and they should be the same length.
- **...**: arguments to be passed to methods and perhaps then to **axis**.

**Details**

This is a generic function. It works in a slightly non-standard way: if \(x\) is supplied and non-NULL it dispatches on \(x\), otherwise if \(at\) is supplied and non-NULL it dispatches on \(at\), and the default action is to call **axis**, omitting argument \(x\).

The idea is that for plots for which either or both of the axes are numerical but with a special interpretation, the standard plotting functions (including `boxplot`, `contour`, `coplot`, `filled.contour`, `pairs`, `plot.default`, `rug` and `stripchart`) will set up user coordinates and **Axis** will be called to label them appropriately.

There are "Date" and "POSIXt" methods which can pass an argument **format** on to the appropriate **axis** method (see **axis.POSIXct**).

**Value**

The numeric locations on the axis scale at which tick marks were drawn when the plot was first drawn (see ‘Details’).

This function is usually invoked for its side effect, which is to add an axis to an already existing plot.

**See Also**

- **axis** (which is eventually called from all **Axis()** methods) in package **graphics**.
Add an Axis to a Plot

Description

Adds an axis to the current plot, allowing the specification of the side, position, labels, and other options.

Usage

axis(side, at = NULL, labels = TRUE, tick = TRUE, line = NA, pos = NA, outer = FALSE, font = NA, lty = "solid", lwd = 1, lwd.ticks = lwd, col = NULL, col.ticks = NULL, hadj = NA, padj = NA, gap.axis = NA, ...)

Arguments

side an integer specifying which side of the plot the axis is to be drawn on. The axis is placed as follows: 1=below, 2=left, 3=above and 4=right.
at the points at which tick-marks are to be drawn. Non-finite (infinite, NaN or NA) values are omitted. By default (when NULL) tickmark locations are computed, see 'Details' below.
labels this can either be a logical value specifying whether (numerical) annotations are to be made at the tickmarks, or a character or expression vector of labels to be placed at the tickpoints. (Other objects are coerced by as.graphicsAnnot.) If this is not logical, at should also be supplied and of the same length. If labels is of length zero after coercion, it has the same effect as supplying TRUE.
tick a logical value specifying whether tickmarks and an axis line should be drawn.
line the number of lines into the margin at which the axis line will be drawn, if not NA.
pos the coordinate at which the axis line is to be drawn: if not NA this overrides the value of line.
outer a logical value indicating whether the axis should be drawn in the outer plot margin, rather than the standard plot margin.
font font for text. Defaults to par("font").
lty line type for both the axis line and the tick marks.
1wd, lwd.ticks line widths for the axis line and the tick marks. Zero or negative values will suppress the line or ticks.
col, col.ticks colors for the axis line and the tick marks respectively. col = NULL means to use par("fg"), possibly specified inline, and col.ticks = NULL means to use whatever color col resolved to.
hadj adjustment (see par("adj")) for all labels parallel ('horizontal') to the reading direction. If this is not a finite value, the default is used (centring for strings parallel to the axis, justification of the end nearest the axis otherwise).
padj adjustment for each tick label perpendicular to the reading direction. For labels parallel to the axes, padj = 0 means right or top alignment, and padj = 1 means left or bottom alignment. This can be a vector given a value for each string, and will be recycled as necessary.
If \( \text{padj} \) is not a finite value (the default), the value of \scode{par("las")} determines the adjustment. For strings plotted perpendicular to the axis the default is to centre the string.

\begin{verbatim}
gap.axis <- if(perpendicular(side, las)) 0.25 else 1
gap.axis may typically be relevant when at = \ldots{} tick-mark positions are specified explicitly.
\end{verbatim}

... other graphical parameters may also be passed as arguments to this function, particularly, \scode{cex.axis}, \scode{col.axis} and \scode{font.axis} for axis annotation, i.e. tick labels, \scode{mgp} and \scode{xaxp} or \scode{yaxp} for positioning, \scode{tck} or \scode{tcl} for tick mark length and direction, \scode{las} for vertical/horizontal label orientation, or \scode{fg} instead of \scode{col}, and \scode{xpd} for clipping. See \scode{par} on these.

Parameters \scode{xaxt} (sides 1 and 3) and \scode{yaxt} (sides 2 and 4) control if the axis is plotted at all. Note that \scode{lab} will partial match to argument \scode{labels} unless the latter is also supplied. (Since the default axes have already been set up by \scode{plot.window}, \scode{lab} will not be acted on by \scode{axis}.)

### Details

The axis line is drawn from the lowest to the highest value of \scode{at}, but will be clipped at the plot region. By default, only ticks which are drawn from points within the plot region (up to a tolerance for rounding error) are plotted, but the ticks and their labels may well extend outside the plot region. Use \scode{xpd = TRUE} or \scode{xpd = NA} to allow axes to extend further.

When \scode{at = NULL}, pretty tick mark locations are computed internally (the same way \scode{axTicks(side)} would) from \scode{par("xaxp")} or \scode{"yaxp"} and \scode{par("xlog")} (or "ylog"). Note that these locations may change if an on-screen plot is resized (for example, if the \scode{plot} argument \scode{asp} (see \scode{plot.window}) is set.)

If \scode{labels} is not specified, the numeric values supplied or calculated for \scode{at} are converted to character strings as if they were a numeric vector printed by \scode{print.default(digits = 7)}.

The code tries hard not to draw overlapping tick labels, and so will omit labels where they would abut or overlap previously drawn labels. This can result in, for example, every other tick being labelled. The ticks are drawn left to right or bottom to top, and space at least the size of an ‘m’, multiplied by \scode{gap.axis}, is left between labels. In previous \proglang{R} versions, this applied only for labels written \textit{parallel} to the axis direction, hence not for e.g., \scode{las = 2}. Using \scode{gap.axis = -1} restores that (buggy) previous behaviour (in the perpendicular case).

If either \scode{line} or \scode{pos} is set, they (rather than \scode{par("mgp")}[3]) determine the position of the axis line and tick marks, and the tick labels are placed \scode{par("mgp")}[2] further lines into (or towards for \scode{pos}) the margin.

Several of the graphics parameters affect the way axes are drawn. The vertical (for sides 1 and 3) positions of the axis and the tick labels are controlled by \scode{mgp}[2:3] and \scode{mex}, the size and direction of
the ticks is controlled by tck and tcl and the appearance of the tick labels by cex.axis, col.axis and font.axis with orientation controlled by las (but not srt, unlike S which uses srt if at is supplied and las if it is not). Note that adj is not supported and labels are always centered. See \code{par} for details.

**Value**

The numeric locations on the axis scale at which tick marks were drawn when the plot was first drawn (see ‘Details’).

This function is usually invoked for its side effect, which is to add an axis to an already existing plot.

**References**

**See Also**

\code{Axis} for a generic interface.

\code{axTicks} returns the axis tick locations corresponding to \code{at = NULL}; \code{pretty} is more flexible for computing pretty tick coordinates and does not depend on (nor adapt to) the coordinate system in use.

Several graphics parameters affecting the appearance are documented in \code{par}.

**Examples**

```r
require(stats) # for rnorm
plot(1:4, rnorm(4), axes = FALSE)
axis(1, 1:4, LETTERS[1:4])
axis(2)
box() #- to make it look "as usual"

plot(1:7, rnorm(7), main = "axis() examples",
    type = "s", xaxt = "n", frame = FALSE, col = "red")
axis(1, 1:7, LETTERS[1:7], col.axis = "blue")
# unusual options:
axis(4, col = "violet", col.axis = "dark violet", lwd = 2)
axis(3, col = "gold", lty = 2, lwd = 0.5)

# one way to have a custom x axis
plot(1:10, xaxt = "n")
axis(1, xaxp = c(2, 9, 7))

## Changing default gap between labels:
plot(0:100, type="n", axes=FALSE, ann=FALSE)
title(quote("axis(1, ..., gap.axis = f),", ~ f > 0))
axis(2, at = 5*0:20, las = 1, gap.axis = 1/4)
gaps <- c(4, 2, 1, 1/2, 1/4, 0.1, 0)
chG <- paste0(ifelse(gaps == 1, "default: ", ""),
    "gap.axis="", formatC(gaps))
jj <- seq_along(gaps)
linG <- -2.5*(jj-1)
for(j in jj) {
    isD <- gaps[j] == 1  # is default
```
axis.POSIXct

Date and Date-time Plotting Functions

Description

Functions to plot objects of classes "POSIXlt", "POSIXct" and "Date" representing calendar dates and times.

Usage

axis.POSIXct(side, x, at, format, labels = TRUE, ...)
axis.Date(side, x, at, format, labels = TRUE, ...)

Arguments

x, at A date-time or date object.
side See \texttt{axis}.
format See \texttt{strptime}.
labels Either a logical value specifying whether annotations are to be made at the tickmarks, or a vector of character strings to be placed at the tickpoints.
... Further arguments to be passed from or to other methods, typically graphical parameters.

Details

\texttt{axis.POSIXct} and \texttt{axis.Date} work quite hard to choose suitable time units (years, months, days, hours, minutes or seconds) and a sensible output format, but this can be overridden by supplying a \texttt{format} specification.

If at is supplied it specifies the locations of the ticks and labels whereas if \texttt{x} is specified a suitable grid of labels is chosen. Printing of tick labels can be suppressed by using \texttt{labels = FALSE}.

The date-times for a "POSIXct" input are interpreted in the time zone give by the "tzone" attribute if there is one, otherwise the current time zone.

The way the date-times are rendered (especially month names) is controlled by the locale setting of category "LC\_TIME" (see \texttt{Sys.setlocale}).

Value

The locations on the axis scale at which tick marks were drawn.

See Also

\texttt{DateTimeClasses, Dates} for details of the classes.

\texttt{Axis}. 
Examples

```r
with(beaver1, {
  time <- strptime(paste(1990, day, time %/% 100, time %% 100),
                   "%Y %d %H %M")
  plot(time, temp, type = "l") # axis at 4-hour intervals.
  # now label every hour on the time axis
  plot(time, temp, type = "l", xaxt = "n")
  r <- as.POSIXct(round(range(time), "hours"))
  axis.POSIXct(1, at = seq(r[1], r[2], by = "hour"), format = "%H")
})

plot(.leap.seconds, seq_along(.leap.seconds), type = "n", yaxt = "n",
     xlab = "leap seconds", ylab = "", bty = "n")
rug(.leap.seconds)
## or as dates
lps <- as.Date(.leap.seconds)
plot(lps, seq_along(.leap.seconds),
     type = "n", yaxt = "n", xlab = "leap seconds",
     ylab = "", bty = "n")
rug(lps)
## 100 random dates in a 10-week period
random.dates <- as.Date("2001/1/1") + 70*sort(stats::runif(100))
plot(random.dates, 1:100)
# or for a better axis labelling
plot(random.dates, 1:100, xaxt = "n")
axis.Date(1, at = seq(as.Date("2001/1/1"), max(random.dates)+6, "weeks"))
axis.Date(1, at = seq(as.Date("2001/1/1"), max(random.dates)+6, "days"),
          labels = FALSE, tcl = -0.2)
```
axTicks

log logical indicating if log coordinates are active; defaults to par("xlog") or par("ylog") depending on side.
nintLog (only used when log is true): approximate (lower bound for the) number of tick intervals; defaults to par("lab")[j] where j is 1 or 2 depending on side. Set this to Inf if you want the same behavior as in earlier R versions (than 2.14.x).

Details

The axp, usr, and log arguments must be consistent as their default values (the par(...) results) are. If you specify all three (as non-NULL), the graphics environment is not used at all. Note that the meaning of axp differs significantly when log is TRUE; see the documentation on par(xaxp = .).

axTicks() may be seen as an R implementation of the C function CreateAtVector() in ../src/main/plot.c which is called by axis(side,*) when no argument at is specified or directly by axisTicks() (in package grDevices).

The delicate case, log = TRUE, now makes use of axisTicks unless nintLog = Inf which exists for back compatibility.

Value

numeric vector of coordinate values at which axis tickmarks can be drawn. By default, when only the first argument is specified, these values should be identical to those that axis(side) would use or has used. Note that the values are decreasing when usr is ("reverse axis" case).

See Also

axis, par, pretty uses the same algorithm (but independently of the graphics environment) and has more options. However it is not available for log = TRUE.

axisTicks() (package grDevices).

Examples

plot(1:7, 1e21:27)
axTicks(1)
axTicks(2)
stopifnot(identical(axTicks(1), axTicks(3)),
identical(axTicks(2), axTicks(4)))

## Show how axTicks() and axis() correspond :
op <- par(mfrow = c(3, 1))
for(x in 9999 * c(1, 2, 8)) {
  plot(x, 9, log = "x")
  cat(formatC(par("xaxp"), width = 5),","a T <- axTicks(1),"\n")
  rug(T, col = adjustcolor("red", 0.5), lwd = 4)
}
par(op)

x <- 9.9*10^(-3:10)
plot(x, 1:14, log = "x")
axTicks(1) # now length 5, in R <= 2.13.x gave the following
axTicks(1, nintLog = Inf) # rather too many

## An example using axTicks() without reference to an existing plot
## (copying R's internal procedures for setting axis ranges etc.),
## You do need to supply _all_ of axp, usr, log, nintLog
## standard logarithmic y axis labels
ylims <- c(0.2, 88)
get_axp <- function(x) 10^c(ceiling(x[1]), floor(x[2]))
## mimic par("yaxs") == "i"
usr.i <- log10(ylims)
(aT.i <- axTicks(side = 2, usr = usr.i,
    ap = c(get_axp(usr.i), n = 3), log = TRUE, nintLog = 5))
## mimic (default) par("yaxs") == "r"
usr.r <- extendrange(r = log10(ylims), f = 0.04)
(aT.r <- axTicks(side = 2, usr = usr.r,
    ap = c(get_axp(usr.r), 3), log = TRUE, nintLog = 5))
## Prove that we got it right :
plot(0:1, ylims, log = "y", yaxs = "i")
stopifnot(all.equal(aT.i, axTicks(side = 2)))
plot(0:1, ylims, log = "y", yaxs = "r")
stopifnot(all.equal(aT.r, axTicks(side = 2)))

### Description

Creates a bar plot with vertical or horizontal bars.

### Usage

```r
barplot(height, ...)  # Default S3 method:

### S3 method for class 'formula'
barplot(formula, data, subset, na.action, horiz = FALSE, xlab = NULL, ylab = NULL, ...)  # S3 method for 'formula'
```

### Arguments

- `height` either a vector or matrix of values describing the bars which make up the plot. If `height` is a vector, the plot consists of a sequence of rectangular bars with heights given by the values in the vector. If `height` is a matrix and `beside` is `FALSE` then each bar of the plot corresponds to a column of `height`, with the
values in the column giving the heights of stacked sub-bars making up the bar. If height is a matrix and beside is TRUE, then the values in each column are juxtaposed rather than stacked.

**width**
optional vector of bar widths. Re-cycled to length the number of bars drawn. Specifying a single value will have no visible effect unless xlim is specified.

**space**
the amount of space (as a fraction of the average bar width) left before each bar. May be given as a single number or one number per bar. If height is a matrix and beside is TRUE, space may be specified by two numbers, where the first is the space between bars in the same group, and the second the space between the groups. If not given explicitly, it defaults to c(0, 1) if height is a matrix and beside is TRUE, and to 0.2 otherwise.

**names.arg**
a vector of names to be plotted below each bar or group of bars. If this argument is omitted, then the names are taken from the names attribute of height if this is a vector, or the column names if it is a matrix.

**legend.text**
a vector of text used to construct a legend for the plot, or a logical indicating whether a legend should be included. This is only useful when height is a matrix. In that case given legend labels should correspond to the rows of height; if legend.text is true, the row names of height will be used as labels if they are non-null.

**beside**
a logical value. If FALSE, the columns of height are portrayed as stacked bars, and if TRUE the columns are portrayed as juxtaposed bars.

**horiz**
a logical value. If FALSE, the bars are drawn vertically with the first bar to the left. If TRUE, the bars are drawn horizontally with the first at the bottom.

**density**
a vector giving the density of shading lines, in lines per inch, for the bars or bar components. The default value of NULL means that no shading lines are drawn. Non-positive values of density also inhibit the drawing of shading lines.

**angle**
the slope of shading lines, given as an angle in degrees (counter-clockwise), for the bars or bar components.

**col**
a vector of colors for the bars or bar components. By default, grey is used if height is a vector, and a gamma-corrected grey palette if height is a matrix.

**border**
the color to be used for the border of the bars. Use border = NA to omit borders. If there are shading lines, border = TRUE means use the same colour for the border as for the shading lines.

**main, sub**
overall and sub title for the plot.

**xlab, ylab**
a label for the x axis.

**xlim, ylim**
limits for the x axis.

**xpd**
logical. Should bars be allowed to go outside region?

**log**
string specifying if axis scales should be logarithmic; see plot.default.

**axes**
logical. If TRUE, a vertical (or horizontal, if horiz is true) axis is drawn.

**axisnames**
logical. If TRUE, and if there are names.arg (see above), the other axis is drawn (with lty = 0) and labeled.

**cex.axis**
expansion factor for numeric axis labels (see par('cex')).

**cex.names**
expansion factor for axis names (bar labels).
inside logical. If TRUE, the lines which divide adjacent (non-stacked!) bars will be drawn. Only applies when space = 0 (which it partly is when beside = TRUE).

plot logical. If FALSE, nothing is plotted.

axis.lty the graphics parameter lty (see par(lty)) applied to the axis and tick marks of the categorical (default horizontal) axis. Note that by default the axis is suppressed.

offset a vector indicating how much the bars should be shifted relative to the x axis.

add logical specifying if bars should be added to an already existing plot; defaults to FALSE.

ann logical specifying if the default annotation (main, sub, xlab, ylab) should appear on the plot, see title.

args.legend list of additional arguments to pass to legend(); names of the list are used as argument names. Only used if legend.text is supplied.

formula a formula where the y variables are numeric data to plot against the categorical x variables. The formula can have one of three forms:

\[
\begin{align*}
  y & \sim x \\
  y & \sim x1 + x2 \\
  \text{cbind}(y1, y2) & \sim x
\end{align*}
\]

(see the examples).

data a data frame (or list) from which the variables in formula should be taken.

subset an optional vector specifying a subset of observations to be used.

na.action a function which indicates what should happen when the data contain NA values. The default is to ignore missing values in the given variables.

... arguments to be passed to/from other methods. For the default method these can include further arguments (such as axes, asp and main) and graphical parameters (see par) which are passed to plot.window(), title() and axis.

Value

A numeric vector (or matrix, when beside = TRUE), say mp, giving the coordinates of all the bar midpoints drawn, useful for adding to the graph.

If beside is true, use colMeans(mp) for the midpoints of each group of bars, see example.

Author(s)

R Core, with a contribution by Arni Magnusson.

              cex.names = 1.5)
segments(mp, hh, mp, hh + 2*sqrt(1000*hh/100), col = mybarcol, lwd = 1.5)
stopifnot(dim(mp) == dim(hh)) # corresponding matrices
mtext(side = 1, at = colMeans(mp), line = -2,
       text = paste("Mean", formatC(colMeans(hh))), col = "red")

# Bar shading example
barplot(VADeaths, angle = 15+10*1:5, density = 20, col = "black",
        pch = 0, main = "Barplot of VADeaths")
```

legend = rownames(VADeaths))
title(main = list("Death Rates in Virginia", font = 4))

# Border color
barplot(VADeaths, border = "dark blue")

# Log scales (not much sense here)
barplot(tN, col = heat.colors(12), log = "y")
barplot(tN, col = gray.colors(20), log = "xy")

# Legend location
barplot(height = cbind(x = c(465, 91) / 465 * 100,
                      y = c(840, 200) / 840 * 100,
                      z = c(37, 17) / 37 * 100),
        beside = FALSE,
        width = c(465, 840, 37),
        col = c(1, 2),
        legend.text = c("A", "B"),
        args.legend = list(x = "topleft"))

box

**Draw a Box around a Plot**

**Description**

This function draws a box around the current plot in the given color and linetype. The `bty` parameter determines the type of box drawn. See `par` for details.

**Usage**

```r
box(which = "plot", lty = "solid", ...)
```

**Arguments**

- `which` character, one of "plot", "figure", "inner" and "outer".
- `lty` line type of the box.
- `...` further graphical parameters, such as `bty`, `col`, or `lwd`, see `par`. Note that `xpd` is not accepted as clipping is always to the device region.

**Details**

The choice of colour is complicated. If `col` was supplied and is not NA, it is used. Otherwise, if `fg` was supplied and is not NA, it is used. The final default is `par("col")`.

**References**

**See Also**

`rect` for drawing of arbitrary rectangles.
Examples

```r
plot(1:7, abs(stats::rnorm(7)), type = "h", axes = FALSE)
axis(1, at = 1:7, labels = letters[1:7])
box(lty = "1373", col = "red")
```

Description

Produce box-and-whisker plot(s) of the given (grouped) values.

Usage

```r
boxplot(x, ...) 
```

## S3 method for class 'formula'

```r
boxplot(formula, data = NULL, ..., subset, na.action = NULL,
        xlab = mklab(y_var = horizontal),
        ylab = mklab(y_var = !horizontal),
        add = FALSE, ann = !add, horizontal = FALSE,
        drop = FALSE, sep = ".", lex.order = FALSE)
```

## Default S3 method:

```r
boxplot(x, ..., range = 1.5, width = NULL, varwidth = FALSE,
        notch = FALSE, outline = TRUE, names, plot = TRUE,
        border = par("fg"), col = "lightgray", log = "",
        pars = list(boxwex = 0.8, staplewex = 0.5, outwex = 0.5),
        ann = !add, horizontal = FALSE, add = FALSE, at = NULL)
```

Arguments

- **formula**
  - a formula, such as `y ~ grp`, where `y` is a numeric vector of data values to be split into groups according to the grouping variable `grp` (usually a factor). Note that `~ g1 + g2` is equivalent to `g1:g2`.
- **data**
  - a data.frame (or list) from which the variables in `formula` should be taken.
- **subset**
  - an optional vector specifying a subset of observations to be used for plotting.
- **na.action**
  - a function which indicates what should happen when the data contain `NA` s. The default is to ignore missing values in either the response or the group.
- **xlab, ylab**
  - x- and y-axis annotation, since R 3.6.0 with a non-empty default. Can be suppressed by `ann=FALSE`.
- **ann**
  - logical indicating if axes should be annotated (by `xlab` and `ylab`).
- **drop, sep, lex.order**
  - passed to `split.default`, see there.
- **x**
  - for specifying data from which the boxplots are to be produced. Either a numeric vector, or a single list containing such vectors. Additional unnamed arguments specify further data as separate vectors (each corresponding to a component boxplot). `NA`s are allowed in the data.
... For the formula method, named arguments to be passed to the default method.

For the default method, unnamed arguments are additional data vectors (unless x
is a list when they are ignored), and named arguments are arguments and graphical
data to be passed to bxp in addition to the ones given by argument
data (and override those in pars). Note that bxp may or may not make use of
argument parameters it is passed: see its documentation.

`range` this determines how far the plot whiskers extend out from the box. If range is
positive, the whiskers extend to the most extreme data point which is no more
than range times the interquartile range from the box. A value of zero causes
the whiskers to extend to the data extremes.

`width` a vector giving the relative widths of the boxes making up the plot.

`varwidth` if varwidth is TRUE, the boxes are drawn with widths proportional to the square-
roots of the number of observations in the groups.

`notch` if notch is TRUE, a notch is drawn in each side of the boxes. If the notches of
two plots do not overlap this is ‘strong evidence’ that the two medians differ

`outline` if outline is not true, the outliers are not drawn (as points whereas S+ uses
lines).

`names` group labels which will be printed under each boxplot. Can be a character vector
or an expression (see plotmath).

`boxwex` a scale factor to be applied to all boxes. When there are only a few groups, the
appearance of the plot can be improved by making the boxes narrower.

`staplewex` staple line width expansion, proportional to box width.

`outwex` outlier line width expansion, proportional to box width.

`plot` if TRUE (the default) then a boxplot is produced. If not, the summaries which the
boxplots are based on are returned.

`border` an optional vector of colors for the outlines of the boxplots. The values in
border are recycled if the length of border is less than the number of plots.

`col` if col is non-null it is assumed to contain colors to be used to colour the bodies
of the box plots. By default they are in the background colour.

`log` character indicating if x or y or both coordinates should be plotted in log scale.

`pars` a list of (potentially many) more graphical parameters, e.g., boxwex or outpch;
these are passed to bxp (if plot is true); for details, see there.

`horizontal` logical indicating if the boxplots should be horizontal; default FALSE means
vertical boxes.

`add` logical, if true add boxplot to current plot.

`at` numeric vector giving the locations where the boxplots should be drawn, particular-
y when add = TRUE; defaults to 1:n where n is the number of boxes.

Details

The generic function boxplot currently has a default method (boxplot.default) and a formula
interface (boxplot.formula).

If multiple groups are supplied either as multiple arguments or via a formula, parallel boxplots will
be plotted, in the order of the arguments or the order of the levels of the factor (see factor).

Missing values are ignored when forming boxplots.
Value
List with the following components:

- **stats**
  - a matrix, each column contains the extreme of the lower whisker, the lower hinge, the median, the upper hinge and the extreme of the upper whisker for one group/plot. If all the inputs have the same class attribute, so will this component.

- **n**
  - a vector with the number of (non-NA) observations in each group.

- **conf**
  - a matrix where each column contains the lower and upper extremes of the notch.

- **out**
  - the values of any data points which lie beyond the extremes of the whiskers.

- **group**
  - a vector of the same length as `out` whose elements indicate to which group the outlier belongs.

- **names**
  - a vector of names for the groups.

References

See also `boxplot.stats`.

See Also
- `boxplot.stats` which does the computation, `bxp` for the plotting and more examples; and `stripchart` for an alternative (with small data sets).

Examples
```r
## boxplot on a formula:
boxplot(count ~ spray, data = InsectSprays, col = "lightgray")
# *add* notches (somewhat funny here <-> warning "notches .. outside hinges"):
boxplot(count ~ spray, data = InsectSprays,
notch = TRUE, add = TRUE, col = "blue")

boxplot(decrease ~ treatment, data = OrchardSprays, col = "bisque",
log = "y")
## horizontal=TRUE, switching y <-> x :
boxplot(decrease ~ treatment, data = OrchardSprays, col = "bisque",
log = "x", horizontal=TRUE)

rb <- boxplot(decrease ~ treatment, data = OrchardSprays, col = "bisque")
title("Comparing boxplot()s and non-robust mean +/- SD")
mm.t <- tapply(OrchardSprays$decrease, OrchardSprays$treatment, mean)
sd.t <- tapply(OrchardSprays$decrease, OrchardSprays$treatment, sd)
xi <- 0.3 + seq(rb$n)
points(xi, mm.t, col = "orange", pch = 18)
arrows(xi, mm.t - sd.t, xi, mm.t + sd.t,
      code = 3, col = "pink", angle = 75, length = .1)

## boxplot on a matrix:
mat <- cbind(Uni05 = (1:100)/21, Norm = rnorm(100),
```
boxplot(matrix)

'ST' = rt(100, df = 5), Gam2 = rgamma(100, shape = 2)
boxplot(mat) # directly, calling boxplot.matrix()

## boxplot on a data frame:
df. <- as.data.frame(mat)
par(las = 1) # all axis labels horizontal
boxplot(df., main = "boxplot(*, horizontal = TRUE)", horizontal = TRUE)

## Using 'at =' and adding boxplots -- example idea by Roger Bivand:
boxplot(len ~ dose, data = ToothGrowth,
        boxwex = 0.25, at = 1:3 - 0.2,
        subset = supp == "VC", col = "yellow",
        main = "Guinea Pigs' Tooth Growth",
        xlab = "Vitamin C dose mg",
        ylab = "tooth length",
        ylim = c(0.5, 3.5), yaxs = "i")
boxplot(len ~ dose, data = ToothGrowth, add = TRUE,
        boxwex = 0.25, at = 1:3 + 0.2,
        subset = supp == "OJ", col = "orange")
legend(2, 9, c("Ascorbic acid", "Orange juice"),
       fill = c("yellow", "orange"))

## With less effort (slightly different) using factor *interaction*:
boxplot(len ~ dose:supp, data = ToothGrowth,
        boxwex = 0.5, col = c("orange", "yellow"),
        main = "Guinea Pigs' Tooth Growth",
        xlab = "Vitamin C dose mg", ylab = "tooth length",
        sep = ":", lex.order = TRUE, ylim = c(0, 35), yaxs = "i")

## more examples in help(bxp)

boxplot.matrix

**Draw a Boxplot for each Column (Row) of a Matrix**

**Description**

Interpreting the columns (or rows) of a matrix as different groups, draw a boxplot for each.

**Usage**

```r
## S3 method for class 'matrix'
boxplot(x, use.cols = TRUE, ...)
```

**Arguments**

- `x` a numeric matrix.
- `use.cols` logical indicating if columns (by default) or rows (use.cols = FALSE) should be plotted.
- `...` Further arguments to `boxplot`.

**Value**

A list as for `boxplot`. 
Author(s)
Martin Maechler, 1995, for S+, then R package sfsmisc.

See Also
boxplot.default which already works nowadays with data.frames, boxplot.formula, plot.factor which work with (the more general concept) of a grouping factor.

Examples
## Very similar to the example in ?boxplot
mat <- cbind(Uni05 = (1:100)/21, Norm = rnorm(100),
             T5 = rt(100, df = 5), Gam2 = rgamma(100, shape = 2))
boxplot(mat, main = "boxplot.matrix(...., main = ...)",
        notch = TRUE, col = 1:4)

Description
bxp draws box plots based on the given summaries in z. It is usually called from within boxplot, but can be invoked directly.

Usage
bxp(z, notch = FALSE, width = NULL, varwidth = FALSE,
    outline = TRUE, notch.frac = 0.5, log = "",
    border = par("fg"), pars = NULL, frame.plot = axes,
    horizontal = FALSE, ann = TRUE,
    add = FALSE, at = NULL, show.names = NULL,
    ...)
log character, indicating if any axis should be drawn in logarithmic scale, as in plot.default.
frame.plot logical, indicating if a ‘frame’ (box) should be drawn; defaults to TRUE, unless axes = FALSE is specified.
horizontal logical indicating if the boxplots should be horizontal; default FALSE means vertical boxes.
ann a logical value indicating whether the default annotation (title and x and y axis labels) should appear on the plot.
add logical, if true add boxplot to current plot.
at numeric vector giving the locations where the boxplots should be drawn, particularly when add = TRUE; defaults to 1:n where n is the number of boxes.
show.names Set to TRUE or FALSE to override the defaults on whether an x-axis label is printed for each group.
pars,\ldots graphical parameters (etc) can be passed as arguments to this function, either as a list (pars) or normally(\ldots), see the following. (Those in \ldots take precedence over those in pars.)
Currently, yaxs and ylim are used ‘along the boxplot’, i.e., vertically, when horizontal is false, and xlim horizontally. xaxt, yaxt, las, cex.axis, and col.axis are passed to axis, and main, cex.main, col.main, sub, cex.sub, col.sub, xlab, ylab, cex.lab, and col.lab are passed to title.
In addition, axes is accepted (see plot.window), with default TRUE.
The following arguments (or pars components) allow further customization of the boxplot graphics. Their defaults are typically determined from the non-prefixed version (e.g., boxlty from lty), either from the specified argument or pars component or the corresponding par one.
boxwex: a scale factor to be applied to all boxes. When there are only a few groups, the appearance of the plot can be improved by making the boxes narrower. The default depends on at and typically is 0.8.
staplewex, outwex: staple and outlier line width expansion, proportional to box width; both default to 0.5.
boxlty, boxlwd, boxcol, boxfill: box outline type, width, color, and fill color (which currently defaults to col and will in future default to par("bg")).
medlty, medlwd, medpch, medcex, medcol, medbg: median line type, line width, point character, point size expansion, color, and background color. The default medpch = NA suppresses the point, and medlty = "blank" does so for the line. Note that medlwd defaults to 3 x the default lwd.
whisklty, whisklwd, whiskcol: whisker line type (default: "dashed"), width, and color.
staplety, staplelwd, staplecol: staple (= end of whisker) line type, width, and color.
outlty, outlwd, outpch, outcex, outcol, outbg: outlier line type, line width, point character, point size expansion, color, and background color. The default outlty = "blank" suppresses the lines and outpch = NA suppresses points.

Value
An invisible vector, actually identical to the at argument, with the coordinates ("x" if horizontal is false, "y" otherwise) of box centers, useful for adding to the plot.
Note

When `add = FALSE`, `xlim` now defaults to `xlim = range(at, *) + c(-0.5, 0.5)`. It will usually be a good idea to specify `xlim` if the "x" axis has a log scale or width is far from uniform.

Author(s)

The R Core development team and Arni Magnusson (then at U Washington) who has provided most changes for the box*, med*, whisk*, staple*, and out* arguments.

Examples

```r
require(stats)
set.seed(753)
(bx.p <- boxplot(split(rt(100, 4), gl(5, 20))))

op <- par(mfrow = c(2, 2))

bxp(bx.p, xaxt = "n")
bxp(bx.p, notch = TRUE, axes = FALSE, pch = 6, boxfill = 1:5)
bxp(bx.p, notch = TRUE, boxfill = "lightblue", frame = FALSE,
    outl = FALSE, main = "bxp(*, frame= FALSE, outl= FALSE)"
)
bxp(bx.p, notch = TRUE, boxfill = "lightblue", border = 2:6,
    ylim = c(-4,4), pch = 22, bg = "green", log = "x",
    main = "... log = 'x', ylim = *")
par(op)

op <- par(mfrow = c(1, 2))

## single group -- no label
boxplot (weight ~ group, data = PlantGrowth, subset = group == "ctrl")
## with label
bx <- boxplot(weight ~ group, data = PlantGrowth,
    subset = group == "ctrl", plot = FALSE)
bxp(bx, show.names=TRUE)
par(op)

z <- split(rnorm(1000), rpois(1000, 2.2))
boxplot(z, whisklty = 3, main = "boxplot(z, whisklty = 3)"
)

## Colour support similar to plot.default:

op <- par(mfrow = 1:2, bg = "light gray", fg = "midnight blue")
boxplot(z, col.axis = "skyblue3", main = "boxplot(*, col.axis=..,main=..)"
)
plot(z[[1]], col.axis = "skyblue3", main = "plot(*, col.axis=..,main=..)"
)
mtext("par(bg="light gray"", fg="midnight blue")",
    outer = TRUE, line = -1.2)
par(op)

## Mimic S-Plus:
splus <- list(boxwex = 0.4, staplewex = 1, outwex = 1, boxfill = "grey40",
    medlwd = 3, medcol = "white", whisklty = 3, outlty = 1, outpch = NA)
boxplot(z, pars = splus)
## Recycled and "sweeping" parameters
op <- par(mfrow = c(1,2))
```
### cdplot

**Conditional Density Plots**

Computes and plots conditional densities describing how the conditional distribution of a categorical variable \( y \) changes over a numerical variable \( x \).

**Usage**

```r
cdplot(x, ...)
```

```r
## Default S3 method:
cdplot(x, y, 
    plot = TRUE, tol.ylab = 0.05, ylevels = NULL,
    bw = "nrd0", n = 512, from = NULL, to = NULL,
    col = NULL, border = 1, main = "", xlab = NULL, ylab = NULL,
    yaxlabels = NULL, xlim = NULL, ylim = c(0, 1), ...)
```

```r
## S3 method for class 'formula'
cdplot(formula, data = list(), 
    plot = TRUE, tol.ylab = 0.05, ylevels = NULL,
    bw = "nrd0", n = 512, from = NULL, to = NULL,
    col = NULL, border = 1, main = "", xlab = NULL, ylab = NULL,
    yaxlabels = NULL, xlim = NULL, ylim = c(0, 1), ..., 
    subset = NULL)
```

**Arguments**

- **x**: an object, the default method expects a single numerical variable (or an object coercible to this).
- **y**: a "factor" interpreted to be the dependent variable
- **formula**: a "formula" of type \( y \sim x \) with a single dependent "factor" and a single numerical explanatory variable.
- **data**: an optional data frame.
- **plot**: logical. Should the computed conditional densities be plotted?
- **tol.ylab**: convenience tolerance parameter for y-axis annotation. If the distance between two labels drops under this threshold, they are plotted equidistantly.
- **ylevels**: a character or numeric vector specifying in which order the levels of the dependent variable should be plotted.
- **bw, n, from, to, ...**: arguments passed to `density`
cdplot

col

a vector of fill colors of the same length as levels(y). The default is to call

gray.colors.

border

border color of shaded polygons.

main, xlab, ylab

character strings for annotation

yaxlabels

character vector for annotation of y axis, defaults to levels(y).

xlim, ylim

the range of x and y values with sensible defaults.

subset

an optional vector specifying a subset of observations to be used for plotting.

Details

cdplot computes the conditional densities of x given the levels of y weighted by the marginal
distribution of y. The densities are derived cumulatively over the levels of y.

This visualization technique is similar to spinograms (see spineplot) and plots \( P(y|x) \) against \( x \).
The conditional probabilities are not derived by discretization (as in the spinogram), but using a
smoothing approach via density.

Note, that the estimates of the conditional densities are more reliable for high-density regions of \( x \).
Conversely, the are less reliable in regions with only few \( x \) observations.

Value

The conditional density functions (cumulative over the levels of y) are returned invisibly.

(spineplot(fail ~ temperature, breaks = 3))
## highlighting for failures

cdplot(fail ~ temperature, ylevels = 2:1)

## scatter plot with conditional density

cdens <- cdplot(fail ~ temperature, plot = FALSE)
plot(I(as.numeric(fail) - 1) ~ jitter(temperature, factor = 2),
    xlab = "Temperature", ylab = "Conditional failure probability")
lines(53:81, 1 - cdens[[1]][53:81], col = 2)

---

### clip

**Set Clipping Region**

**Description**

Set clipping region in user coordinates

**Usage**

`clip(x1, x2, y1, y2)`

**Arguments**

- `x1, x2, y1, y2`  
  user coordinates of clipping rectangle

**Details**

How the clipping rectangle is set depends on the setting of `par("xpd")`: this function changes the current setting until the next high-level plotting command resets it.

Clipping of lines, rectangles and polygons is done in the graphics engine, but clipping of text is if possible done in the device, so the effect of clipping text is device-dependent (and may result in text not wholly within the clipping region being omitted entirely).

Exactly when the clipping region will be reset can be hard to predict. `plot.new` always resets it. Functions such as `lines` and `text` only reset it if `par("xpd")` has been changed. However, functions such as `box`, `mtext`, `title` and `plot.dendrogram` can manipulate the `xpd` setting.

**See Also**

`par`

**Examples**

```r
x <- rnorm(1000)
hist(x, xlim = c(-4,4))
usr <- par("usr")
clip(usr[1], -2, usr[3], usr[4])
hist(x, col = 'red', add = TRUE)
clip(2, usr[2], usr[3], usr[4])
hist(x, col = 'blue', add = TRUE)
do.call("clip", as.list(usr))  # reset to plot region
```
contour

Display Contours

Description
Create a contour plot, or add contour lines to an existing plot.

Usage
contour(x, ...)

## Default S3 method:
contour(x = seq(0, 1, length.out = nrow(z)),
y = seq(0, 1, length.out = ncol(z)),
z,
nlevels = 10, levels = pretty(zlim, nlevels),
labels = NULL,
xlim = range(x, finite = TRUE),
ylim = range(y, finite = TRUE),
zlim = range(z, finite = TRUE),
labcex = 0.6, drawlabels = TRUE, method = "flattest",
vfont, axes = TRUE, frame.plot = axes,
col = par("fg"), lty = par("lty"), lwd = par("lwd"),
add = FALSE, ...)

Arguments

x, y locations of grid lines at which the values in z are measured. These must be in ascending order. By default, equally spaced values from 0 to 1 are used. If x is a list, its components x$x and x$y are used for x and y, respectively. If the list has component z this is used for z.

z a matrix containing the values to be plotted (NAs are allowed). Note that x can be used instead of z for convenience.
nlevels number of contour levels desired iff levels is not supplied.
levels numeric vector of levels at which to draw contour lines.
labels a vector giving the labels for the contour lines. If NULL then the levels are used as labels, otherwise this is coerced by as.character.
labcex cex for contour labelling. This is an absolute size, not a multiple of par("cex").
drawlabels logical. Contours are labelled if TRUE.
method character string specifying where the labels will be located. Possible values are "simple", "edge" and "flattest" (the default). See the 'Details' section.
vfont if NULL, the current font family and face are used for the contour labels. If a character vector of length 2 then Hershey vector fonts are used for the contour labels. The first element of the vector selects a typeface and the second element selects a fontindex (see text for more information). The default is NULL on graphics devices with high-quality rotation of text and c("sans serif","plain") otherwise.
xlim, ylim, zlim x-, y- and z-limits for the plot.
axes, frame.plot  
 logical indicating whether axes or a box should be drawn, see plot.default.

col  
 colour(s) for the lines drawn.

lty  
 line type(s) for the lines drawn.

lwd  
 line width(s) for the lines drawn.

add  
 logical. If TRUE, add to a current plot.

...  
 additional arguments to plot.window, title, Axis and box, typically graphical parameters such as cex.axis.

Details

contour is a generic function with only a default method in base R.

The methods for positioning the labels on contours are "simple" (draw at the edge of the plot, overlaying the contour line), "edge" (draw at the edge of the plot, embedded in the contour line, with no labels overlapping) and "flattest" (draw on the flattest section of the contour, embedded in the contour line, with no labels overlapping). The second and third may not draw a label on every contour line.

For information about vector fonts, see the help for text and Hershey.

Notice that contour interprets the z matrix as a table of f(x[i],y[j]) values, so that the x axis corresponds to row number and the y axis to column number, with column 1 at the bottom, i.e. a 90 degree counter-clockwise rotation of the conventional textual layout.

Vector (of length > 1) col, lty, and lwd are applied along levels and recycled, see the Examples.

Alternatively, use contourplot from the lattice package where the formula notation allows to use vectors x, y, and z of the same length.

There is limited control over the axes and frame as arguments col, lwd and lty refer to the contour lines (rather than being general graphical parameters). For more control, add contours to a plot, or add axes and frame to a contour plot.

options("max.contour.segments") for the maximal complexity of a single contour line.

contourlines, filled.contour for color-filled contours, contourplot (and levelplot) from package lattice. Further, image and the graphics demo which can be invoked as demo(graphics).

Examples

require(grDevices) # for colours
x <- -6:16
op <- par(mfrow = c(2, 2))
contour(outer(x, x), method = "edge", vfont = c("sans serif", "plain"))
z <- outer(x, sqrt(abs(x)), FUN = "/")
image(x, x, z)
contour(x, x, z, col = "pink", add = TRUE, method = "edge",
     vfont = c("sans serif", "plain"))
contour(x, x, z, ylim = c(1, 6), method = "simple", labcex = 1,
     xlab = quote(x[1]), ylab = quote(x[2]))
convertXY

Convert between Graphics Coordinate Systems

Description

Convert between graphics coordinate systems.
Usage

grconvertX(x, from = "user", to = "user")
grconvertY(y, from = "user", to = "user")

Arguments

x, y       numeric vector of coordinates.
from, to   character strings giving the coordinate systems to convert between.

Details

The coordinate systems are

"user"  user coordinates.
"inches" inches.
"device" the device coordinate system.
"ndc"   normalized device coordinates.
"nfc"   normalized figure coordinates.
"npc"   normalized plot coordinates.
"nic"   normalized inner region coordinates. (The ‘inner region’ is that inside the outer margins.)
"lines" lines of margin (based on mex).
"chars" lines of text (based on cex).

(These names can be partially matched.) For the ‘normalized’ coordinate systems the lower left has value 0 and the top right value 1.

Device coordinates are those in which the device works: they are usually in pixels where that makes sense and in big points (1/72 inch) otherwise (e.g., pdf and postscript).

Value

A numeric vector of the same length as the input.

Examples

op <- par(omd=c(0.1, 0.9, 0.1, 0.9), mfrow = c(1, 2))
plot(1:4)
for(tp in c("in", "dev", "ndc", "nfc", "npc", "nic", "lines", "chars"))
  print(grconvertX(c(1.0, 4.0), "user", tp))
par(op)
coplot  Conditioning Plots

Description

This function produces two variants of the conditioning plots discussed in the reference below.

Usage

coplot(formula, data, given.values, panel = points, rows, columns,
show.given = TRUE, col = par("fg"), pch = par("pch"),
bar.bg = c(num = gray(0.8), fac = gray(0.95)),
xlab = c(x.name, paste("Given:", a.name)),
ylab = c(y.name, paste("Given:", b.name)),
subscripts = FALSE,
axlabels = function(f) abbreviate(levels(f)),
number = 6, overlap = 0.5, xlim, ylim, ...)
c.co.intervals(x, number = 6, overlap = 0.5)

Arguments

formula a formula describing the form of conditioning plot. A formula of the form \( y \sim x \mid a \) indicates that plots of \( y \) versus \( x \) should be produced conditional on the variable \( a \). A formula of the form \( y \sim x \mid a \times b \) indicates that plots of \( y \) versus \( x \) should be produced conditional on the two variables \( a \) and \( b \).

All three or four variables may be either numeric or factors. When \( x \) or \( y \) are factors, the result is almost as if as.numeric() was applied, whereas for factor \( a \) or \( b \), the conditioning (and its graphics if show.given is true) are adapted.

data a data frame containing values for any variables in the formula. By default the environment where coplot was called from is used.
given.values a value or list of two values which determine how the conditioning on \( a \) and \( b \) is to take place.

When there is no \( b \) (i.e., conditioning only on \( a \)), usually this is a matrix with two columns each row of which gives an interval, to be conditioned on, but is can also be a single vector of numbers or a set of factor levels (if the variable being conditioned on is a factor). In this case (no \( b \)), the result of co.intervals can be used directly as given.values argument.

panel a function\((x,y,col,pch,...)\) which gives the action to be carried out in each panel of the display. The default is points.

rows the panels of the plot are laid out in a rows by columns array. rows gives the number of rows in the array.
columns the number of columns in the panel layout array.
show.given logical (possibly of length 2 for 2 conditioning variables): should conditioning plots be shown for the corresponding conditioning variables (default TRUE).
col a vector of colors to be used to plot the points. If too short, the values are recycled.
pch a vector of plotting symbols or characters. If too short, the values are recycled.
bar.bg a named vector with components "num" and "fac" giving the background colors for the (shingle) bars, for numeric and factor conditioning variables respectively.

xlab character; labels to use for the x axis and the first conditioning variable. If only one label is given, it is used for the x axis and the default label is used for the conditioning variable.

ylab character; labels to use for the y axis and any second conditioning variable.

subscripts logical: if true the panel function is given an additional (third) argument subscripts giving the subscripts of the data passed to that panel.

axlabels function for creating axis (tick) labels when x or y are factors.

number integer; the number of conditioning intervals, for a and b, possibly of length 2. It is only used if the corresponding conditioning variable is not a factor.

overlap numeric < 1; the fraction of overlap of the conditioning variables, possibly of length 2 for x and y direction. When overlap < 0, there will be gaps between the data slices.

xlim the range for the x axis.

ylim the range for the y axis.

... additional arguments to the panel function.

x a numeric vector.

Details

In the case of a single conditioning variable a, when both rows and columns are unspecified, a 'close to square' layout is chosen with columns >= rows.

In the case of multiple rows, the order of the panel plots is from the bottom and from the left (corresponding to increasing a, typically).

A panel function should not attempt to start a new plot, but just plot within a given coordinate system: thus plot and boxplot are not panel functions.

The rendering of arguments xlab and ylab is not controlled by par arguments cex.lab and font.lab even though they are plotted by mtext rather than title.

Value

co.intervals(. , number , .) returns a (number × 2) matrix, say ci, where ci[k,] is the range of x values for the k-th interval.

References

See Also

pairs, panel.smooth, points.
Examples

```r
## Tonga Trench Earthquakes
coplot(lat ~ long | depth, data = quakes)
given.depth <- co.intervals(quakes$depth, number = 4, overlap = .1)
coplot(lat ~ long | depth, data = quakes, given.v = given.depth, rows = 1)

## Conditioning on 2 variables:
ll.dm <- lat ~ long | depth * mag
coplot(ll.dm, data = quakes)
coplot(ll.dm, data = quakes, number = c(4, 7), show.given = c(TRUE, FALSE))
coplot(ll.dm, data = quakes, number = c(3, 7),
   overlap = c(-.5, .1)) # negative overlap DROPS values

## given two factors
Index <- seq(length = nrow(warpbreaks)) # to get nicer default labels
coplot(breaks ~ Index | wool * tension, data = warpbreaks,
   show.given = 0:1)
coplot(breaks ~ Index | wool * tension, data = warpbreaks,
   col = "red", bg = "pink", pch = 21,
   bar.bg = c(fac = "light blue"))

## Example with empty panels:
with(data.frame(state.x77), {
   coplot(Life.Exp ~ Income | Illiteracy * state.region, number = 3,
      panel = function(x, y, ...) panel.smooth(x, y, span = .8, ...))
   ## y ~ factor -- not really sensible, but 'show off':
   coplot(Life.Exp ~ state.region | Income * state.division,
      panel = panel.smooth)
})
```

curve

Draw Function Plots

Description

Draws a curve corresponding to a function over the interval [from,to]. curve can plot also an expression in the variable xname, default ‘x’.

Usage

```r
curve(expr, from = NULL, to = NULL, n = 101, add = FALSE,
type = "l", xname = "x", xlab = xname, ylab = NULL,
log = NULL, xlim = NULL, ...) 
```

Arguments

- **expr**: The name of a function, or a call or an expression written as a function of x which will evaluate to an object of the same length as x.
- **x**: a 'vectorizing' numeric R function.
- **y**: alias for from for compatibility with plot.
from, to the range over which the function will be plotted.

n integer; the number of x values at which to evaluate.

add logical; if TRUE add to an already existing plot; if NA start a new plot taking the defaults for the limits and log-scaling of the x-axis from the previous plot. Taken as FALSE (with a warning if a different value is supplied) if no graphics device is open.

xlim NULL or a numeric vector of length 2; if non-NULL it provides the defaults for c(from,to) and, unless add = TRUE, selects the x-limits of the plot – see plot.window.

type plot type: see plot.default.

xname character string giving the name to be used for the x axis.

xlab, ylab, log, ... labels and graphical parameters can also be specified as arguments. See ‘Details’ for the interpretation of the default for log.

For the "function" method of plot,... can include any of the other arguments of curve, except expr.

Details

The function or expression expr (for curve) or function x (for plot) is evaluated at n points equally spaced over the range [from, to]. The points determined in this way are then plotted.

If either from or to is NULL, it defaults to the corresponding element of xlim if that is not NULL.

What happens when neither from/to nor xlim specifies both x-limits is a complex story. For plot(<function>) and for curve(add = FALSE) the defaults are (0, 1). For curve(add = NA) and curve(add = TRUE) the defaults are taken from the x-limits used for the previous plot. (This differs from versions of R prior to 2.14.0.)

The value of log is used both to specify the plot axes (unless add = TRUE) and how 'equally spaced' is interpreted: if the x component indicates log-scaling, the points at which the expression or function is plotted are equally spaced on log scale.

The default value of log is taken from the current plot when add = TRUE, whereas if add = NA the x component is taken from the existing plot (if any) and the y component defaults to linear. For add = FALSE the default is "".

This used to be a quick hack which now seems to serve a useful purpose, but can give bad results for functions which are not smooth.

For expensive-to-compute expressions, you should use smarter tools.

The way curve handles expr has caused confusion. It first looks to see if expr is a name (also known as a symbol), in which case it is taken to be the name of a function, and expr is replaced by a call to expr with a single argument with name given by xname. Otherwise it checks that expr is either a call or an expression, and that it contains a reference to the variable given by xname (using all.vars): anything else is an error. Then expr is evaluated in an environment which supplies a vector of name given by xname of length n, and should evaluate to an object of length n. Note that this means that curve(x,...) is taken as a request to plot a function named x (and it is used as such in the function method for plot).

The plot method can be called directly as plot.function.

Value

A list with components x and y of the points that were drawn is returned invisibly.
Warning

For historical reasons, add is allowed as an argument to the "function" method of plot, but its behaviour may surprise you. It is recommended to use add only with curve.

splinefun for spline interpolation, lines.

Examples

plot(qnorm) # default range c(0, 1) is appropriate here,
    # but end values are +/-Inf and so are omitted.
plot(qlogis, main = "The Inverse Logit : qlogis()")
abline(h = 0, v = 0:2/2, lty = 3, col = "gray")

curve(sin, -2*pi, 2*pi, xname = "t")
curve(tan, xname = "t", add = NA,
    main = "curve(tan) --> same x-scale as previous plot")

op <- par(mfrow = c(2, 2))
curve(x^3 - 3*x, -2, 2)
curve(x^2 - 2, add = TRUE, col = "violet")

## simple and advanced versions, quite similar:
plot(cos, -pi, 3*pi)
curve(cos, xlim = c(-pi, 3*pi), n = 1001, col = "blue", add = TRUE)

chippy <- function(x) sin(cos(x)*exp(-x/2))
curve(chippy, -8, 7, n = 2001)
plot (chippy, -8, -5)
for(ll in c("", "x", "y", "xy")){
    curve(log(1+x), 1, 100, log = ll, sub = paste0("log = " , ll, "", ""))
}
par(op)

---

dotchart Cleveland’s Dot Plots

Description

Draw a Cleveland dot plot.

Usage

dotchart(x, labels = NULL, groups = NULL, gdata = NULL, offset = 1/8,
    ann = par("ann"), xaxt = par("xaxt"), frame.plot = TRUE, log = "",
    cex = par("cex"), pt.cex = cex,
    pch = 21, gpch = 21, bg = par("bg"),
    color = par("fg"), gcolor = par("fg"), lcolor = "gray",
    xlim = range(x[is.finite(x)]),
    main = NULL, xlab = NULL, ylab = NULL, ...)
Arguments

- **x**: either a vector or matrix of numeric values (NAs are allowed). If `x` is a matrix the overall plot consists of juxtaposed dotplots for each row. Inputs which satisfy `is.numeric(x)` but not `is.vector(x) || is.matrix(x)` are coerced by `as.numeric`, with a warning.
- **labels**: a vector of labels for each point. For vectors the default is to use `names(x)` and for matrices the row labels `dimnames(x)[[1]]`.
- **groups**: an optional factor indicating how the elements of `x` are grouped. If `x` is a matrix, `groups` will default to the columns of `x`.
- **gdata**: data values for the groups. This is typically a summary such as the median or mean of each group.
- **offset**: offset in inches of `ylab` and labels; was hardwired to 0.4 before R 4.0.0.
- **ann**: a logical value indicating whether the default annotation (title and x and y axis labels) should appear on the plot.
- **xaxt**: a string indicating the x-axis style; use "n" to suppress and see also `par("xaxt")`.
- **frame.plot**: a logical indicating whether a box should be drawn around the plot.
- **log**: a character string indicating if one or the other axis should be logarithmic, see `plot.default`.
- **cex**: the character size to be used. Setting `cex` to a value smaller than one can be a useful way of avoiding label overlap. Unlike many other graphics functions, this sets the actual size, not a multiple of `par("cex")`.
- **pt.cex**: the `cex` to be applied to plotting symbols. This behaves like `cex` in `plot()`.
- **pch**: the plotting character or symbol to be used.
- **gpch**: the plotting character or symbol to be used for group values.
- **bg**: the background color of plotting characters or symbols to be used; use `par(bg=*)` to set the background color of the whole plot.
- **color**: the color(s) to be used for points and labels.
- **gcolor**: the single color to be used for group labels and values.
- **lcolor**: the color(s) to be used for the horizontal lines.
- **xlim**: horizontal range for the plot, see `plot.window`, for example.
- **main**: overall title for the plot, see `title`.
- **xlab, ylab**: axis annotations as in `title`.
- **...**: graphical parameters can also be specified as arguments.

Value

This function is invoked for its side effect, which is to produce two variants of dotplots as described in Cleveland (1985).

Dot plots are a reasonable substitute for bar plots.

Examples

dotchart(VADeaths, main = "Death Rates in Virginia - 1940")

op <- par(xaxs = "i") # 0 -- 100%
dotchart(t(VADeaths), xlim = c(0,100), bg = "skyblue", 
    main = "Death Rates in Virginia - 1940", xlab = "rate [ % ]", 
    ylab = "Grouping: Age x Urbanity . Gender")
par(op)

filled.contour

Level (Contour) Plots

Description

This function produces a contour plot with the areas between the contours filled in solid color (Cleveland calls this a level plot). A key showing how the colors map to z values is shown to the right of the plot.

Usage

filled.contour(x = seq(0, 1, length.out = nrow(z)), 
    y = seq(0, 1, length.out = ncol(z)), 
    z, 
    xlim = range(x, finite = TRUE), 
    ylim = range(y, finite = TRUE), 
    zlim = range(z, finite = TRUE), 
    levels = pretty(zlim, nlevels), nlevels = 20, 
    color.palette = function(n) hcl.colors(n, "YlOrRd", rev = TRUE), 
    col = color.palette(length(levels) - 1), 
    plot.title, plot.axes, key.title, key.axes, 
    asp = NA, xaxs = "i", yaxs = "i", las = 1, 
    axes = TRUE, frame.plot = axes, ...)

.filled.contour(x, y, z, levels, col)

Arguments

x, y
locations of grid lines at which the values in z are measured. These must be in ascending order. (The rest of this description does not apply to .filled.contour.) By default, equally spaced values from 0 to 1 are used. If x is a list, its components x$x and x$y are used for x and y, respectively. If the list has component z this is used for z.

z
a numeric matrix containing the values to be plotted. Note that x can be used instead of z for convenience.

xlim
x limits for the plot.

ylim
y limits for the plot.

zlim
z limits for the plot.

levels
a set of levels which are used to partition the range of z. Must be strictly increasing (and finite). Areas with z values between consecutive levels are painted with the same color.
if `levels` is not specified, the range of `z` values is divided into approximately this many levels.

a color palette function to be used to assign colors in the plot.

an explicit set of colors to be used in the plot. This argument overrides any palette function specification. There should be one less color than levels

statements which add titles to the main plot.

statements which draw axes (and a box) on the main plot. This overrides the default axes.

statements which add titles for the plot key.

statements which draw axes on the plot key. This overrides the default axis.

the y/x aspect ratio, see `plot.window`.

the x axis style. The default is to use internal labeling.

the y axis style. The default is to use internal labeling.

the style of labeling to be used. The default is to use horizontal labeling.

logicals indicating if axes and a box should be drawn, as in `plot.default`.

additional graphical parameters, currently only passed to `title()`.

The values to be plotted can contain NAs. Rectangles with two or more corner values are NA are omitted entirely; where there is a single NA value the triangle opposite the NA is omitted. Values to be plotted can be infinite: the effect is similar to that described for NA values.

`.filled.contour` is a ‘bare bones’ interface to add just the contour plot to an already-set-up plot region. It is is intended for programmatic use, and the programmer is responsible for checking the conditions on the arguments.

filled.contour uses the `layout` function and so is restricted to a full page display.

The output produced by `filled.contour` is actually a combination of two plots; one is the filled contour and one is the legend. Two separate coordinate systems are set up for these two plots, but they are only used internally – once the function has returned these coordinate systems are lost. If you want to annotate the main contour plot, for example to add points, you can specify graphics commands in the `plot.axes` argument. See the examples.

Ross Ihaka and R Core Team

`contour`, `image`, `hcl.colors`, `gray.colors`, `palette`; `contourplot` and `levelplot` from package `lattice`. 

example
Examples

```r
require("grDevices") # for colours
filled.contour(volcano, asp = 1) # simple

x <- 10*1:nrow(volcano)
y <- 10*1:ncol(volcano)
filled.contour(x, y, volcano, color = function(n) hcl.colors(n, "terrain"),
  plot.title = title(main = "The Topography of Maunga Whau"),
  xlab = "Meters North", ylab = "Meters West"),
  plot.axes = { axis(1, seq(100, 800, by = 100))
    axis(2, seq(100, 600, by = 100)) },
  key.title = title(main = "Height\n(meters)"),
  key.axes = axis(4, seq(90, 190, by = 10))) # maybe also asp = 1
mtext(paste("filled.contour(.) from", R.version.string),
  side = 1, line = 4, adj = 1, cex = .66)
```

# Annotating a filled contour plot
```r
a <- expand.grid(1:20, 1:20)
b <- matrix(a[,1] + a[,2], 20)
filled.contour(x = 1:20, y = 1:20, z = b,
  plot.axes = { axis(1); axis(2); points(10, 10) })
```

## Persian Rug Art:
```r
x <- y <- seq(-4*pi, 4*pi, len = 27)
r <- sqrt(outer(x^2, y^2, "+")
filled.contour(cos(r^2)*exp(-r/(2*pi)), axes = FALSE)
## rather, the key *should* be labeled:
filled.contour(cos(r^2)*exp(-r/(2*pi)), frame.plot = FALSE,
  plot.axes = { })
```

---

fourfoldplot

### Fourfold Plots

**Description**

Creates a fourfold display of a 2 by 2 by $k$ contingency table on the current graphics device, allowing for the visual inspection of the association between two dichotomous variables in one or several populations (strata).

**Usage**

```r
fourfoldplot(x, color = c("#99CCFF", ":6699CC"),
  conf.level = 0.95,
  std = c("margins", "ind.max", "all.max"),
  margin = c(1, 2), space = 0.2, main = NULL,
  mfrow = NULL, mfcol = NULL)
```

**Arguments**

- `x` a 2 by 2 by $k$ contingency table in array form, or as a 2 by 2 matrix if $k$ is 1.
- `color` a vector of length 2 specifying the colors to use for the smaller and larger diagonals of each 2 by 2 table.
conf.level  confidence level used for the confidence rings on the odds ratios. Must be a single nonnegative number less than 1; if set to 0, confidence rings are suppressed.

std  a character string specifying how to standardize the table. Must match one of "margins", "ind.max", or "all.max", and can be abbreviated to the initial letter. If set to "margins", each 2 by 2 table is standardized to equate the margins specified by margin while preserving the odds ratio. If "ind.max" or "all.max", the tables are either individually or simultaneously standardized to a maximal cell frequency of 1.

margin  a numeric vector with the margins to equate. Must be one of 1, 2, or c(1,2) (the default), which corresponds to standardizing the row, column, or both margins in each 2 by 2 table. Only used if std equals "margins".

space  the amount of space (as a fraction of the maximal radius of the quarter circles) used for the row and column labels.

main  character string for the fourfold title.

mfrow  a numeric vector of the form c(nr,nc), indicating that the displays for the 2 by 2 tables should be arranged in an nr by nc layout, filled by rows.

mfcol  a numeric vector of the form c(nr,nc), indicating that the displays for the 2 by 2 tables should be arranged in an nr by nc layout, filled by columns.

Details

The fourfold display is designed for the display of 2 by 2 by k tables. Following suitable standardization, the cell frequencies f_{ij} of each 2 by 2 table are shown as a quarter circle whose radius is proportional to \sqrt{f_{ij}} so that its area is proportional to the cell frequency. An association (odds ratio different from 1) between the binary row and column variables is indicated by the tendency of diagonally opposite cells in one direction to differ in size from those in the other direction; color is used to show this direction. Confidence rings for the odds ratio allow a visual test of the null of no association; the rings for adjacent quadrants overlap if and only if the observed counts are consistent with the null hypothesis.

Typically, the number k corresponds to the number of levels of a stratifying variable, and it is of interest to see whether the association is homogeneous across strata. The fourfold display visualizes the pattern of association. Note that the confidence rings for the individual odds ratios are not adjusted for multiple testing.

---

### frame

Create / Start a New Plot Frame

**Description**

This function \( \text{frame} \) (is an alias for \( \text{plot.new} \)) causes the completion of plotting in the current plot (if there is one) and an advance to a new graphics frame. This is used in all high-level plotting functions and also useful for skipping plots when a multi-figure region is in use.

**Usage**

\[ \text{plot.new}() \]
\[ \text{frame}() \]

**Details**

The new page is painted with the background colour \( \text{par} \("bg"\) \), which is often transparent. For devices with a \text{canvas} colour (the on-screen devices \text{X11}, \text{windows} and \text{quartz}), the window is first painted with the canvas colour and then the background colour.

There are two hooks called \"before.plot.new\" and \"plot.new\" (see \text{setHook}) called immediately before and after advancing the frame. The latter is used in the testing code to annotate the new page. The hook function(s) are called with no argument. (If the value is a character string, \text{get} is called on it from within the \text{graphics} namespace.)

**References**

\[ \text{plot.window}, \text{plot.default}. \]
grid

Add Grid to a Plot

Description

grid adds an nx by ny rectangular grid to an existing plot.

Usage

grid(nx = NULL, ny = nx, col = "lightgray", lty = "dotted",
     lwd = par("lwd"), equilogs = TRUE)

Arguments

nx, ny  number of cells of the grid in x and y direction. When NULL, as per default, the grid aligns with the tick marks on the corresponding default axis (i.e., tickmarks as computed by axTicks). When NA, no grid lines are drawn in the corresponding direction.

col character or (integer) numeric; color of the grid lines.

lty character or (integer) numeric; line type of the grid lines.

lwd non-negative numeric giving line width of the grid lines.

equilogs logical, only used when log coordinates and alignment with the axis tick marks are active. Setting equilogs = FALSE in that case gives non equidistant tick aligned grid lines.

Note

If more fine tuning is required, use abline(h = ., v = .) directly.

References

See Also

plot, abline, lines, points.

Examples

plot(1:3)
grid(NA, 5, lwd = 2) # grid only in y-direction

## maybe change the desired number of tick marks: par(lab = c(mx, my, 7))
op <- par(mfcol = 1:2)
with(iris,
    {
    plot(Sepal.Length, Sepal.Width, col = as.integer(Species),
         xlim = c(4, 8), ylim = c(2, 4.5), panel.first = grid(),
         main = "with(iris, plot(...., panel.first = grid(), .. ) )")
    plot(Sepal.Length, Sepal.Width, col = as.integer(Species),
         panel.first = grid(3, lty = 1, lwd = 2),
         main = "... panel.first = grid(3, lty = 1, lwd = 2), ..")
    }
The generic function `hist` computes a histogram of the given data values. If `plot = TRUE`, the resulting object of class "histogram" is plotted by `plot.histogram`, before it is returned.

### Usage

```r
hist(x, ...) 
```

### Arguments

- **x**: a vector of values for which the histogram is desired.
- **breaks**: one of:
  - a vector giving the breakpoints between histogram cells,
  - a function to compute the vector of breakpoints,
  - a single number giving the number of cells for the histogram,
  - a character string naming an algorithm to compute the number of cells (see ‘Details’),
  - a function to compute the number of cells.

In the last three cases the number is a suggestion only; as the breakpoints will be set to pretty values, the number is limited to 1e6 (with a warning if it was larger). If `breaks` is a function, the `x` vector is supplied to it as the only argument (and the number of breaks is only limited by the amount of available memory).

- **freq**: logical; if `TRUE`, the histogram graphic is a representation of frequencies, the counts component of the result;
  if `FALSE`, probability densities, component density, are plotted (so that the histogram has a total area of one). Defaults to `TRUE if and only if` `breaks` are equidistant (and `probability` is not specified).

- **probability**: an alias for `!freq`, for S compatibility.
include.lowest

logical; if TRUE, an \( x[i] \) equal to the breaks value will be included in the first (or last, for right = FALSE) bar. This will be ignored (with a warning) unless breaks is a vector.

right

logical; if TRUE, the histogram cells are right-closed (left open) intervals.

density

the density of shading lines, in lines per inch. The default value of NULL means that no shading lines are drawn. Non-positive values of density also inhibit the drawing of shading lines.

angle

the slope of shading lines, given as an angle in degrees (counter-clockwise).

col

a colour to be used to fill the bars. The default of NULL yields unfilled bars.

border

the color of the border around the bars. The default is to use the standard foreground color.

main, xlab, ylab

main title and axis labels: these arguments to title() get “smart” defaults here, e.g., the default ylab is “Frequency” iff freq is true.

xlim, ylim

the range of x and y values with sensible defaults. Note that xlim is not used to define the histogram (breaks), but only for plotting (when plot = TRUE).

axes

logical. If TRUE (default), axes are draw if the plot is drawn.

plot

logical. If TRUE (default), a histogram is plotted, otherwise a list of breaks and counts is returned. In the latter case, a warning is used if (typically graphical) arguments are specified that only apply to the plot = TRUE case.

labels

logical or character string. Additionally draw labels on top of bars, if not FALSE; see plot.histogram.

nclass

numeric (integer). For S(-PLUS) compatibility only, nclass is equivalent to breaks for a scalar or character argument.

warn.unused

logical. If plot = FALSE and warn.unused = TRUE, a warning will be issued when graphical parameters are passed to hist.default().

...

further arguments and graphical parameters passed to plot.histogram and thence to title and axis (if plot = TRUE).

Details

The definition of histogram differs by source (with country-specific biases). R’s default with equi-spaced breaks (also the default) is to plot the counts in the cells defined by breaks. Thus the height of a rectangle is proportional to the number of points falling into the cell, as is the area provided the breaks are equally-spaced.

The default with non-equi-spaced breaks is to give a plot of area one, in which the area of the rectangles is the fraction of the data points falling in the cells.

If right = TRUE (default), the histogram cells are intervals of the form \((a,b]\), i.e., they include their right-hand endpoint, but not their left one, with the exception of the first cell when include.lowest is TRUE.

For right = FALSE, the intervals are of the form \([a,b)\), and include.lowest means ‘include highest’.

A numerical tolerance of \(10^{-7}\) times the median bin size (for more than four bins, otherwise the median is substituted) is applied when counting entries on the edges of bins. This is not included in the reported breaks nor in the calculation of density.

The default for breaks is "Sturges": see nclass.Sturges. Other names for which algorithms are supplied are "Scott" and "FD" / "Freedman-Diaconis" (with corresponding functions...
nclass.scott and nclass.FD). Case is ignored and partial matching is used. Alternatively, a function can be supplied which will compute the intended number of breaks or the actual breakpoints as a function of x.

Value

an object of class "histogram" which is a list with components:

- breaks the n + 1 cell boundaries (= breaks if that was a vector). These are the nominal breaks, not with the boundary fuzz.
- counts n integers; for each cell, the number of x[] inside.
- density values \( \hat{f}(x_i) \), as estimated density values. If all(diff(breaks) == 1), they are the relative frequencies counts/n and in general satisfy \( \sum_i \hat{f}(x_i)(b_{i+1} - b_i) = 1 \), where \( b_i = \text{breaks}[i] \).
- mids the n cell midpoints.
- xname a character string with the actual x argument name.
- equidist logical, indicating if the distances between breaks are all the same.

References

See Also

nclass.Sturges, stem, density, truehist in package MASS.

Typical plots with vertical bars are not histograms. Consider barplot or plot(*, type = "h") for such bar plots.

Examples

```r
op <- par(mfrow = c(2, 2))
hist(islands)
utils::str(hist(islands, col = "gray", labels = TRUE))

hist(sort(islands), breaks = 12, col = "lightblue", border = "pink")
##-- For non-equidistant breaks, counts should NOT be graphed unscaled:
r <- hist(sort(islands), breaks = c(4*0:5, 10*3:5, 70, 100, 140),
          col = "blue1")
text(r$mids, r$density, r$counts, adj = c(.5, -.5), col = "blue3")
sapply(r[2:3], sum)
sum(r$density * diff(r$breaks)) # == 1
lines(r, lty = 3, border = "purple") # -> lines.histogram(*)
par(op)

require(stats) # for str
str(hist(islands, breaks = 12, plot = FALSE)) #-> 10 (~= 12) breaks
str(hist(islands, breaks = c(12,20,36,80,200,1000,17000), plot = FALSE))

hist(islands, breaks = c(12,20,36,80,200,1000,17000), freq = TRUE,
main = "WRONG histogram") # and warning
```
Extreme outliers; the "FD" rule would take very large number of 'breaks':

```r
XXL <- c(1:9, c(-1,1)*1e300)
hh <- hist(XXL, "FD") # did not work in R <= 3.4.1; now gives warning
```

Pretty() determines how many counts are used (platform dependently!):

```r
length(hh$breaks) ## typically 1 million -- though 1e6 was "a suggestion only"
```

```r
require(stats)
set.seed(14)
x <- rchisq(100, df = 4)
```

Comparing data with a model distribution should be done with `qqplot()`!

```r
qqplot(x, qchisq(ppoints(x), df = 4)); abline(0, 1, col = 2, lty = 2)
```

If you really insist on using `hist()` ...:

```r
hist(x, freq = FALSE, ylim = c(0, 0.2))
curve(dchisq(x, df = 4), col = 2, lty = 2, lwd = 2, add = TRUE)
```

## hist.POSIXt

### Histogram of a Date or Date-Time Object

**Description**

Method for `hist` applied to date or date-time objects.

**Usage**

```r
## S3 method for class 'POSIXt'
hist(x, breaks, ..., 
  xlab = deparse1(substitute(x)),
  plot = TRUE, freq = FALSE,
  start.on.monday = TRUE, format, right = TRUE)
```

```r
## S3 method for class 'Date'
hist(x, breaks, ..., 
  xlab = deparse1(substitute(x)),
  plot = TRUE, freq = FALSE,
  start.on.monday = TRUE, format, right = TRUE)
```

**Arguments**

- `x` an object inheriting from class "POSIXt" or "Date".
- `breaks` a vector of cut points or number giving the number of intervals which `x` is to be cut into or an interval specification, one of "days", "weeks", "months", "quarters" or "years", plus "secs", "mins", "hours" for date-time objects.
- `...` graphical parameters, or arguments to `hist.default` such as `include.lowest`, `right` and `labels`.
- `xlab` a character string giving the label for the x axis, if plotted.
- `plot` logical. If `TRUE` (default), a histogram is plotted, otherwise a list of breaks and counts is returned.
freq
logical; if TRUE, the histogram graphic is a representation of frequencies, i.e., the counts component of the result; if FALSE, relative frequencies (probabilities) are plotted.

start.on.monday
logical. If breaks = "weeks", should the week start on Mondays or Sundays?

format
for the x-axis labels. See `strptime`.

right
logical; if TRUE, the histogram cells are right-closed (left open) intervals.

Details
Note that unlike the default method, `breaks` is a required argument.

Using `breaks = "quarters"` will create intervals of 3 calendar months, with the intervals beginning on January 1, April 1, July 1 or October 1, based upon min(x) as appropriate.

With the default `right = TRUE`, breaks will be set on the last day of the previous period when `breaks` is "months", "quarters" or "years". Use `right = FALSE` to set them to the first day of the interval shown in each bar.

Value
An object of class "histogram": see `hist`.

See Also
`seq.POSIXt, axis.POSIXct, hist`

Examples
```
hist(.leap.seconds, "years", freq = TRUE)
hist(.leap.seconds,
    seq(ISOdate(1970, 1, 1), ISOdate(2020, 1, 1), "5 years"))
rug(.leap.seconds, lwd=2)

## 100 random dates in a 10-week period
random.dates <- as.Date("2001/1/1") + 70*stats::runif(100)
hist(random.dates, "weeks", format = "%d %b")
```

**identify**

**Identify Points in a Scatter Plot**

**Description**
`identify` reads the position of the graphics pointer when the (first) mouse button is pressed. It then searches the coordinates given in `x` and `y` for the point closest to the pointer. If this point is close enough to the pointer, its index will be returned as part of the value of the call.

**Usage**
```
identify(x, ...)
```

## Default S3 method:
```
identify(x, y = NULL, labels = seq_along(x), pos = FALSE,
    n = length(x), plot = TRUE, atpen = FALSE,
    offset = 0.5, tolerance = 0.25, order = FALSE, ...)
```
Arguments

- **x, y**: coordinates of points in a scatter plot. Alternatively, any object which defines coordinates (a plotting structure, time series etc: see `xy.coords`) can be given as x, and y left missing.

- **labels**: an optional character vector giving labels for the points. Will be coerced using `as.character`, and recycled if necessary to the length of x. Excess labels will be discarded, with a warning.

- **pos**: if pos is TRUE, a component is added to the return value which indicates where text was plotted relative to each identified point: see Value.

- **n**: the maximum number of points to be identified.

- **plot**: logical: if plot is TRUE, the labels are printed near the points and if FALSE they are omitted.

- **atpen**: logical: if TRUE and plot = TRUE, the lower-left corners of the labels are plotted at the points clicked rather than relative to the points.

- **offset**: the distance (in character widths) which separates the label from identified points. Negative values are allowed. Not used if atpen = TRUE.

- **tolerance**: the maximal distance (in inches) for the pointer to be ‘close enough’ to a point.

- **order**: if order is TRUE, a component is added to the return value which indicates the order in which points were identified: see Value.

- **...**: further arguments passed to `par` such as cex, col and font.

Details

`identify` is a generic function, and only the default method is described here.

`identify` is only supported on screen devices such as X11, windows and quartz. On other devices the call will do nothing.

Clicking near (as defined by tolerance) a point adds it to the list of identified points. Points can be identified only once, and if the point has already been identified or the click is not near any of the points a message is printed immediately on the R console.

If plot is TRUE, the point is labelled with the corresponding element of labels. If atpen is false (the default) the labels are placed below, to the left, above or to the right of the identified point, depending on where the pointer was relative to the point. If atpen is true, the labels are placed with the bottom left of the string’s box at the pointer.

For the usual X11 device the identification process is terminated by pressing any mouse button other than the first. For the quartz device the process is terminated by pressing either the pop-up menu equivalent (usually second mouse button or Ctrl-click) or the ESC key.

On most devices which support `identify`, successful selection of a point is indicated by a bell sound unless `options(locatorBell = FALSE)` has been set.

If the window is resized or hidden and then exposed before the identification process has terminated, any labels drawn by identify will disappear. These will reappear once the identification process has terminated and the window is resized or hidden and exposed again. This is because the labels drawn by `identify` are not recorded in the device’s display list until the identification process has terminated.

If you interrupt the `identify` call this leaves the graphics device in an undefined state, with points labelled but labels not recorded in the display list. Copying a device in that state will give unpredictable results.
Value

If both pos and order are FALSE, an integer vector containing the indices of the identified points.
If either of pos or order is TRUE, a list containing a component ind, indicating which points were identified and (if pos is TRUE) a component pos, indicating where the labels were placed relative to the identified points (1=below, 2=left, 3=above, 4=right and 0=no offset, used if atpen = TRUE) and (if order is TRUE) a component order, indicating the order in which points were identified.

Technicalities

The algorithm used for placing labels is the same as used by text if pos is specified there, the difference being that the position of the pointer relative the identified point determines pos in identify.

For labels placed to the left of a point, the right-hand edge of the string’s box is placed offset units to the left of the point, and analogously for points to the right. The baseline of the text is placed below the point so as to approximately centre string vertically. For labels placed above or below a point, the string is centered horizontally on the point. For labels placed above, the baseline of the text is placed offset units above the point, and for those placed below, the baseline is placed so that the top of the string’s box is approximately offset units below the point. If you want more precise placement (e.g., centering) use plot = FALSE and plot via text or points: see the examples.

Display a Color Image

Description

Creates a grid of colored or gray-scale rectangles with colors corresponding to the values in \( z \). This can be used to display three-dimensional or spatial data aka images. This is a generic function.

**NOTE:** the grid is drawn as a set of rectangles by default; see the `useRaster` argument to draw the grid as a raster image.

The function `hcl.colors` provides a broad range of sequential color palettes that are suitable for displaying ordered data, with \( n \) giving the number of colors desired.

Usage

image(x, ...)

## Default S3 method:
image(x, y, z, zlim, xlim, ylim,
col = hcl.colors(12, "YlOrRd", rev = TRUE),
add = FALSE, xaxs = "i", yaxs = "i", xlab, ylab,
breaks, oldstyle = FALSE, useRaster, ...)

Arguments

- **x, y**: locations of grid lines at which the values in \( z \) are measured. These must be finite, non-missing and in (strictly) ascending order. By default, equally spaced values from 0 to 1 are used. If \( x \) is a list, its components \( x$x \) and \( x$y \) are used for \( x \) and \( y \), respectively. If the list has component \( z \) this is used for \( z \).
- **z**: a numeric or logical matrix containing the values to be plotted (NAs are allowed). Note that \( x \) can be used instead of \( z \) for convenience.
- **zlim**: the minimum and maximum \( z \) values for which colors should be plotted, defaulting to the range of the finite values of \( z \). Each of the given colors will be used to color an equispaced interval of this range. The midpoints of the intervals cover the range, so that values just outside the range will be plotted.
- **xlim, ylim**: ranges for the plotted \( x \) and \( y \) values, defaulting to the ranges of \( x \) and \( y \).
- **col**: a list of colors such as that generated by `hcl.colors`, `gray.colors` or similar functions.
- **add**: logical; if TRUE, add to current plot (and disregard the following four arguments). This is rarely useful because `image` 'paints' over existing graphics.
- **xaxs, yaxs**: style of \( x \) and \( y \) axis. The default "i" is appropriate for images. See `par`.
- **xlab, ylab**: each a character string giving the labels for the \( x \) and \( y \) axis. Default to the ‘call names’ of \( x \) or \( y \), or to "" if these were unspecified.
- **breaks**: a set of finite numeric breakpoints for the colours: must have one more breakpoint than colour and be in increasing order. Unsorted vectors will be sorted, with a warning.
- **oldstyle**: logical. If true the midpoints of the colour intervals are equally spaced, and \( zlim[1] \) and \( zlim[2] \) were taken to be midpoints. The default is to have colour intervals of equal lengths between the limits.
useRaster

Use a bitmap raster instead of polygons. The grid must be regular in that case, otherwise an error is raised. For the behaviour when this is not specified, see ‘Details’.

... graphical parameters for plot may also be passed as arguments to this function, as can the plot aspect ratio asp and axes (see plot.window).

Details

The length of x should be equal to the nrow(z)+1 or nrow(z). In the first case x specifies the boundaries between the cells: in the second case x specifies the midpoints of the cells. Similar reasoning applies to y. It probably only makes sense to specify the midpoints of an equally-spaced grid. If you specify just one row or column and a length-one x or y, the whole user area in the corresponding direction is filled. For logarithmic x or y axes the boundaries between cells must be specified.

Rectangles corresponding to missing values are not plotted (and are transparent and (unless add = TRUE) the default background painted in par("bg") will show through and if that is transparent, the canvas colour will be seen).

If breaks is specified then zlim is unused and the algorithm used follows cut, so intervals are closed on the right and open on the left except for the lowest interval which is closed at both ends.

The axes (where plotted) make use of the classes of xlim and ylim (and hence by default the classes of x and y): this will mean that for example dates are labelled as such.

Notice that image interprets the z matrix as a table of f(x[i],y[j]) values, so that the x axis corresponds to row number and the y axis to column number, with column 1 at the bottom, i.e. a 90 degree counter-clockwise rotation of the conventional printed layout of a matrix.

Images for large z on a regular grid are rendered more efficiently with useRaster = TRUE and can prevent rare anti-aliasing artifacts, but may not be supported by all graphics devices. Some devices (such as postscript and X11(type = "Xlib")) which do not support semi-transparent colours may emit missing values as white rather than transparent, and there may be limitations on the size of a raster image. (Problems with the rendering of raster images have been reported by users of windows() devices under Remote Desktop, at least under its default settings.)

The graphics files in PDF and PostScript can be much smaller under this option.

If useRaster is not specified, raster images are used when thegetOption("preferRaster") is true, the grid is regular and either dev.capabilities("rasterImage")$rasterImage is "yes” or it is "non-missing” and there are no missing values.

Note

Originally based on a function by Thomas Lumley.

layout

---

**Specifying Complex Plot Arrangements**

**Description**

`layout` divides the device up into as many rows and columns as there are in matrix `mat`, with the column-widths and the row-heights specified in the respective arguments.

**Usage**

```r
layout(mat, widths = rep.int(1, ncol(mat)),
       heights = rep.int(1, nrow(mat)), respect = FALSE)
```

**Arguments**

- `mat` a matrix object specifying the location of the next $N$ figures on the output device. Each value in the matrix must be 0 or a positive integer. If $N$ is the largest positive integer in the matrix, then the integers $\{1, \ldots, N-1\}$ must also appear at least once in the matrix.

- `widths` a vector of values for the widths of columns on the device. Relative widths are specified with numeric values. Absolute widths (in centimetres) are specified with the `lcm()` function (see examples).

- `heights` a vector of values for the heights of rows on the device. Relative and absolute heights can be specified, see `widths` above.

- `respect` either a logical value or a matrix object. If the latter, then it must have the same dimensions as `mat` and each value in the matrix must be either 0 or 1.

- `n` number of figures to plot.

- `x` a dimension to be interpreted as a number of centimetres.
Details

Figure \( i \) is allocated a region composed from a subset of these rows and columns, based on the rows and columns in which \( i \) occurs in \( \text{mat} \).

The respect argument controls whether a unit column-width is the same physical measurement on the device as a unit row-height.

There is a limit (currently 200) for the numbers of rows and columns in the layout, and also for the total number of cells (10007).

\( \text{layout.show}(n) \) plots (part of) the current layout, namely the outlines of the next \( n \) figures.

\( \text{lcm} \) is a trivial function, to be used as the interface for specifying absolute dimensions for the widths and heights arguments of \( \text{layout()} \).

Value

\( \text{layout} \) returns the number of figures, \( N \), see above.

Warnings

These functions are totally incompatible with the other mechanisms for arranging plots on a device: \( \text{par(mfrow)} \), \( \text{par(mfcol)} \) and \( \text{split.screen} \).

**legend**

**Add Legends to Plots**

**Description**

This function can be used to add legends to plots. Note that a call to the function `locator(1)` can be used in place of the `x` and `y` arguments.

**Usage**

```r
legend(x, y = NULL, legend, fill = NULL, col = par("col"),
       border = "black", lty, lwd, pch,
       angle = 45, density = NULL, bty = "o", bg = par("bg"),
       box.lwd = par("lwd"), box.lty = par("lty"), box.col = par("fg"),
       pt.bg = NA, cex = 1, pt.cex = cex, pt.lwd = lwd,
       xjust = 0, yjust = 1, x.intersp = 1, y.intersp = 1,
       adj = c(0, 0.5), text.width = NULL, text.col = par("col"),
       text.font = NULL, merge = do.lines && has.pch, trace = FALSE,
       plot = TRUE, ncol = 1, horiz = FALSE, title = NULL,
       inset = 0, xpd, title.col = text.col, title.adj = 0.5,
       seg.len = 2)
```

**Arguments**

- `x, y` the x and y co-ordinates to be used to position the legend. They can be specified by keyword or in any way which is accepted by `xy.coords`: See ‘Details’.
- `legend` a character or `expression` vector of length ≥ 1 to appear in the legend. Other objects will be coerced by `as.graphicsAnnot`. 

---
fill  if specified, this argument will cause boxes filled with the specified colors (or shaded in the specified colors) to appear beside the legend text.

col  the color of points or lines appearing in the legend.

border  the border color for the boxes (used only if fill is specified).

lty, lwd  the line types and widths for lines appearing in the legend. One of these two must be specified for line drawing.

pch  the plotting symbols appearing in the legend, as numeric vector or a vector of 1-character strings (see points). Unlike points, this can all be specified as a single multi-character string. Must be specified for symbol drawing.

angle  angle of shading lines.

density  the density of shading lines, if numeric and positive. If NULL or negative or NA color filling is assumed.

bty  the type of box to be drawn around the legend. The allowed values are "o" (the default) and "n".

bg  the background color for the legend box. (Note that this is only used if bty != "n".)

box.lty, box.lwd, box.col  the line type, width and color for the legend box (if bty = "o").

pt.bg  the background color for the points, corresponding to its argument bg.

cex  character expansion factor relative to current par("cex"). Used for text, and provides the default for pt.cex.

pt.cex  expansion factor(s) for the points.

pt.lwd  line width for the points, defaults to the one for lines, or if that is not set, to par("lwd").

xjust  how the legend is to be justified relative to the legend x location. A value of 0 means left justified, 0.5 means centered and 1 means right justified.

yjust  the same as xjust for the legend y location.

x.intersp  character interspacing factor for horizontal (x) spacing.

y.intersp  the same for vertical (y) line distances.

adj  numeric of length 1 or 2; the string adjustment for legend text. Useful for y-adjustment when labels are plotmath expressions.

text.width  the width of the legend text in x ("user") coordinates. (Should be a single positive number even for a reversed x axis.) Defaults to the proper value computed by strwidth(legend).

text.col  the color used for the legend text.

text.font  the font used for the legend text, see text.

merge  logical; if TRUE, merge points and lines but not filled boxes. Defaults to TRUE if there are points and lines.

trace  logical; if TRUE, shows how legend does all its magical computations.

plot  logical. If FALSE, nothing is plotted but the sizes are returned.

ncol  the number of columns in which to set the legend items (default is 1, a vertical legend).

horiz  logical; if TRUE, set the legend horizontally rather than vertically (specifying horiz overrides the ncol specification).
title a character string or length-one expression giving a title to be placed at the top of the legend. Other objects will be coerced by `as.graphicsAnnot`.

inset inset distance(s) from the margins as a fraction of the plot region when legend is placed by keyword.

xpd if supplied, a value of the graphical parameter `xpd` to be used while the legend is being drawn.

title.col color for title.

title.adj horizontal adjustment for title: see the help for `par("adj")`.

seg.len the length of lines drawn to illustrate `lty` and/or `lwd` (in units of character widths).

Details

Arguments `x`, `y`, `legend` are interpreted in a non-standard way to allow the coordinates to be specified via one or two arguments. If `legend` is missing and `y` is not numeric, it is assumed that the second argument is intended to be `legend` and that the first argument specifies the coordinates.

The coordinates can be specified in any way which is accepted by `xy.coords`. If this gives the coordinates of one point, it is used as the top-left coordinate of the rectangle containing the legend. If it gives the coordinates of two points, these specify opposite corners of the rectangle (either pair of corners, in any order).

The location may also be specified by setting `x` to a single keyword from the list "bottomright", "bottom", "bottomleft", "left", "topleft", "top", "topright", "right", and "center". This places the legend on the inside of the plot frame at the given location. Partial argument matching is used. The optional `inset` argument specifies how far the legend is inset from the plot margins. If a single value is given, it is used for both margins; if two values are given, the first is used for `x`-distance, the second for `y`-distance.

Attribute arguments such as `col`, `pch`, `lty`, etc, are recycled if necessary: `merge` is not. Set entries of `lty` to 0 or set entries of `lwd` to NA to suppress lines in corresponding legend entries; set `pch` values to NA to suppress points.

Points are drawn after lines in order that they can cover the line with their background color `pt.bg`, if applicable.

See the examples for how to right-justify labels.

Since they are not used for Unicode code points, values -31:-1 are silently omitted, as are NA and "" values.

Value

A list with list components

`rect` a list with components

  `w`, `h` positive numbers giving width and height of the legend’s box.

  `left`, `top` x and y coordinates of upper left corner of the box.

`text` a list with components

  `x`, `y` numeric vectors of length `length(legend)`, giving the x and y coordinates of the legend’s text(s).

returned invisibly.

### lines

**Add Connected Line Segments to a Plot**

#### Description

A generic function taking coordinates given in various ways and joining the corresponding points with line segments.

#### Usage

```r
lines(x, ...)```

#### Arguments

- `x, y` coordinate vectors of points to join.
- `type` character indicating the type of plotting; actually any of the types as in `plot.default`.
- `...` Further graphical parameters (see `par`) may also be supplied as arguments, particularly, line type, 1ty, line width, lwd, color, col and for `type = "b"`, pch. Also the line characteristics lend, ljoin and lmitre.

#### Details

The coordinates can be passed in a plotting structure (a list with `x` and `y` components), a two-column matrix, a time series, .... See `xy.coords`. If supplied separately, they must be of the same length.

The coordinates can contain NA values. If a point contains NA in either its `x` or `y` value, it is omitted from the plot, and lines are not drawn to or from such points. Thus missing values can be used to achieve breaks in lines.
For type = "h", col can be a vector and will be recycled as needed.

lwd can be a vector: its first element will apply to lines but the whole vector to symbols (recycled as necessary).

References

See Also

\texttt{lines.formula} for the formula method; \texttt{points}, particularly for type \texttt{c("p","b","o")}, \texttt{plot}, and the workhorse function \texttt{plot.xy}. \texttt{abline} for drawing (single) straight lines. \texttt{par} for line type (lty) specification and how to specify colors.

Examples

\begin{verbatim}
# draw a smooth line through a scatter plot
plot(cars, main = "Stopping Distance versus Speed")
lines(stats::lowess(cars))
\end{verbatim}

locator

\textit{Graphical Input}

\textbf{Description}

Reads the position of the graphics cursor when the (first) mouse button is pressed.

\textbf{Usage}

\texttt{locator(n = 512, type = "n", \ldots)}

\textbf{Arguments}

- \texttt{n} the maximum number of points to locate. Valid values start at 1.
- \texttt{type} One of "n", "p", "l" or "o". If "p" or "o" the points are plotted; if "l" or "o" they are joined by lines.
- \texttt{\ldots} additional graphics parameters used if type \texttt{!= "n"} for plotting the locations.

\textbf{Details}

\texttt{locator} is only supported on screen devices such as \texttt{X11}, \texttt{windows} and \texttt{quartz}. On other devices the call will do nothing.

Unless the process is terminated prematurely by the user (see below) at most \texttt{n} positions are determined.

For the usual \texttt{X11} device the identification process is terminated by pressing any mouse button other than the first. For the \texttt{quartz} device the process is terminated by pressing the ESC key.
The current graphics parameters apply just as if `plot.default` has been called with the same value of type. The plotting of the points and lines is subject to clipping, but locations outside the current clipping rectangle will be returned.

On most devices which support `locator`, successful selection of a point is indicated by a bell sound unless `options(locatorBell = FALSE)` has been set.

If the window is resized or hidden and then exposed before the input process has terminated, any lines or points drawn by `locator` will disappear. These will reappear once the input process has terminated and the window is resized or hidden and exposed again. This is because the points and lines drawn by `locator` are not recorded in the device’s display list until the input process has terminated.

**Value**

A list containing x and y components which are the coordinates of the identified points in the user coordinate system, i.e., the one specified by `par("usr")`.

**References**

**See Also**

`identify`, `grid.locator` is the corresponding `grid` package function.

`dev.capabilities` to see if it is supported.

---

**matplot**

*Plot Columns of Matrices*

**Description**

Plot the columns of one matrix against the columns of another (which often is just a vector treated as 1-column matrix).

**Usage**

```r
matplot(x, y, type = "p", lty = 1:5, lwd = 1, lend = par("lend"),
pch = NULL,
col = 1:6, cex = NULL, bg = NA,
xlab = NULL, ylab = NULL, xlim = NULL, ylim = NULL,
log = "", ..., add = FALSE, verbose = getOption("verbose"))
```

```r
matpoints(x, y, type = "p", lty = 1:5, lwd = 1, pch = NULL,
col = 1:6, ...)```

```r
matlines(x, y, type = "l", lty = 1:5, lwd = 1, pch = NULL,
col = 1:6, ...)```

```r
matplot(x, y, type = "p", lty = 1:5, lwd = 1, lend = par("lend"),
pch = NULL,
col = 1:6, cex = NULL, bg = NA,
xlab = NULL, ylab = NULL, xlim = NULL, ylim = NULL,
log = "", ..., add = FALSE, verbose = getOption("verbose"))
```
Arguments

x, y: vectors or matrices of data for plotting. The number of rows should match. If one of them is missing, the other is taken as y and an x vector of 1:n is used. Missing values (NAs) are allowed. Since R 4.0.0, class(·)es of x and y such as "Date" are typically preserved.

type: character string (length 1 vector) or vector of 1-character strings indicating the type of plot for each column of y, see plot for all possible types. The first character of type defines the first plot, the second character the second, etc. Characters in type are cycled through; e.g., "pl" alternately plots points and lines.

lty, lwd, lend: vector of line types, widths, and end styles. The first element is for the first column, the second element for the second column, etc., even if lines are not plotted for all columns. Line types will be used cyclically until all plots are drawn.

pch: character string or vector of 1-characters or integers for plotting characters, see points for details. The first character is the plotting-character for the first plot, the second for the second, etc. The default is the digits (1 through 9, 0) then the lowercase and uppercase letters.

col: vector of colors. Colors are used cyclically.

cex: vector of character expansion sizes, used cyclically. This works as a multiple of par("cex"). NULL is equivalent to 1.0.

bg: vector of background (fill) colors for the open plot symbols given by pch = 21:25 as in points. The default NA corresponds to the one of the underlying function plot.xy.

xlab, ylab: titles for x and y axes, as in plot.

xlim, ylim: ranges of x and y axes, as in plot.

log, ...: Graphical parameters (see par) and any further arguments of plot, typically plot.default, may also be supplied as arguments to this function; even panel.first etc now work. Hence, the high-level graphics control arguments described under par and the arguments to title may be supplied to this function.

add: logical. If TRUE, plots are added to current one, using points and lines.

verbose: logical. If TRUE, write one line of what is done.

Details

matplot(x,y,...) is basically a wrapper for

1. calling (the generic function) plot(x[,1],y[,1],...) for the first columns (only if add = TRUE).

2. calling (the generic) lines(x[,j],y[,j],...) for subsequent columns.

Since R 4.0.0, care is taken to keep the class(·) of x and y, such that the corresponding plot() and lines() methods will be called.

Points involving missing values are not plotted.

The first column of x is plotted against the first column of y, the second column of x against the second column of y, etc. If one matrix has fewer columns, plotting will cycle back through the columns again. (In particular, either x or y may be a vector, against which all columns of the other argument will be plotted.)
The first element of col, cex, lty, lwd is used to plot the axes as well as the first line. Because plotting symbols are drawn with lines and because these functions may be changing the line style, you should probably specify lty = 1 when using plotting symbols.

Side Effects

Function matplot generates a new plot; matpoints and matlines add to the current one.

dimnames = list(NULL, nam.var, nam.spec))
for(i in 1:3) iris.S[,,i] <- data.matrix(iris[1:50+50*(i-1), -5])
```
mosaicplot

Description

Plots a mosaic on the current graphics device.

Usage

mosaicplot(x, ...)  

# Default S3 method:
mosaicplot(x, main = deparse1(substitute(x)),  
          sub = NULL, xlab = NULL, ylab = NULL,  
          sort = NULL, off = NULL, dir = NULL,  
          color = NULL, shade = FALSE, margin = NULL,  
          cex.axis = 0.66, las = par("las"), border = NULL,  
          type = c("pearson", "deviance", "FT"), ...)  

# S3 method for class 'formula'
mosaicplot(formula, data = NULL, ...,  
          main = deparse1(substitute(data)), subset,  
          na.action = stats::na.omit)

Arguments

x  

a contingency table in array form, with optional category labels specified in the dimnames(x) attribute. The table is best created by the table() command.

main  

character string for the mosaic title.

sub  

character string for the mosaic sub-title (at bottom).
mosaicplot

xlab, ylab x- and y-axis labels used for the plot; by default, the first and second element of names(dimnames(X)) (i.e., the name of the first and second variable in X).

sort vector ordering of the variables, containing a permutation of the integers 1:length(dim(x)) (the default).

off vector of offsets to determine percentage spacing at each level of the mosaic (appropriate values are between 0 and 20, and the default is 20 times the number of splits for 2-dimensional tables, and 10 otherwise). Rescaled to maximally 50, and recycled if necessary.

dir vector of split directions ("v" for vertical and "h" for horizontal) for each level of the mosaic, one direction for each dimension of the contingency table. The default consists of alternating directions, beginning with a vertical split.

color logical or (recycling) vector of colors for color shading, used only when shade is FALSE, or NULL (default). By default, grey boxes are drawn. color = TRUE uses a gamma-corrected grey palette. color = FALSE gives empty boxes with no shading.

shade a logical indicating whether to produce extended mosaic plots, or a numeric vector of at most 5 distinct positive numbers giving the absolute values of the cut points for the residuals. By default, shade is FALSE, and simple mosaics are created. Using shade = TRUE cuts absolute values at 2 and 4.

margin a list of vectors with the marginal totals to be fit in the log-linear model. By default, an independence model is fitted. See loglin for further information.

cex.axis The magnification to be used for axis annotation, as a multiple of par("cex").

las numeric; the style of axis labels, see par.

border colour of borders of cells: see polygon.

type a character string indicating the type of residual to be represented. Must be one of "pearson" (giving components of Pearson’s $\chi^2$), "deviance" (giving components of the likelihood ratio $\chi^2$), or "FT" for the Freeman-Tukey residuals. The value of this argument can be abbreviated.

formula a formula, such as y ~ x.

data a data frame (or list), or a contingency table from which the variables in formula should be taken.

... further arguments to be passed to or from methods.

subset an optional vector specifying a subset of observations in the data frame to be used for plotting.

na.action a function which indicates what should happen when the data contains variables to be cross-tabulated, and these variables contain NAs. The default is to omit cases which have an NA in any variable. Since the tabulation will omit all cases containing missing values, this will only be useful if the na.action function replaces missing values.

Details

This is a generic function. It currently has a default method (mosaicplot.default) and a formula interface (mosaicplot.formula).

Extended mosaic displays visualize standardized residuals of a loglinear model for the table by color and outline of the mosaic’s tiles. (Standardized residuals are often referred to a standard normal distribution.) Cells representing negative residuals are drawn in shaded of red and with broken borders; positive ones are drawn in blue with solid borders.
For the formula method, if data is an object inheriting from class "table" or class "ftable" or an array with more than 2 dimensions, it is taken as a contingency table, and hence all entries should be non-negative. In this case the left-hand side of formula should be empty and the variables on the right-hand side should be taken from the names of the dimnames attribute of the contingency table. A marginal table of these variables is computed, and a mosaic plot of that table is produced.

Otherwise, data should be a data frame or matrix, list or environment containing the variables to be cross-tabulated. In this case, after possibly selecting a subset of the data as specified by the subset argument, a contingency table is computed from the variables given in formula, and a mosaic is produced from this.

See Emerson (1998) for more information and a case study with television viewer data from Nielsen Media Research.

Missing values are not supported except via an na.action function when data contains variables to be cross-tabulated.

A more flexible and extensible implementation of mosaic plots written in the grid graphics system is provided in the function mosaic in the contributed package vcd (Meyer, Zeileis and Hornik, 2006).

Author(s)
S-PLUS original by John Emerson <john.emerson@yale.edu>. Originally modified and enhanced for R by Kurt Hornik.

---

**mtext**

*Write Text into the Margins of a Plot*

**Description**

Text is written in one of the four margins of the current figure region or one of the outer margins of the device region.

**Usage**

```r
mtext(text, side = 3, line = 0, outer = FALSE, at = NA,
      adj = NA, padj = NA, cex = NA, col = NA, font = NA, ...)
```

**Arguments**

- `text`: a character or expression vector specifying the text to be written. Other objects are coerced by `as.graphicsAnnot`.
- `side`: on which side of the plot (1=bottom, 2=left, 3=top, 4=right).
- `line`: on which margin line, starting at 0 counting outwards.
- `outer`: use outer margins if available.
- `at`: give location of each string in user coordinates. If the component of `at` corresponding to a particular text item is not a finite value (the default), the location will be determined by `adj`.
- `adj`: adjustment for each string in reading direction. For strings parallel to the axes, `adj = 0` means left or bottom alignment, and `adj = 1` means right or top alignment.
  - If `adj` is not a finite value (the default), the value of `par("las")` determines the adjustment. For strings plotted parallel to the axis the default is to centre the string.
- `padj`: adjustment for each string perpendicular to the reading direction (which is controlled by `adj`). For strings parallel to the axes, `padj = 0` means right or top alignment, and `padj = 1` means left or bottom alignment.
  - If `padj` is not a finite value (the default), the value of `par("las")` determines the adjustment. For strings plotted perpendicular to the axis the default is to centre the string.
**mtext**

character expansion factor. NULL and NA are equivalent to 1.0. This is an absolute measure, not scaled by par("cex") or by setting par("mtext") or par("mfcex"). Can be a vector.

col
color to use. Can be a vector. NA values (the default) mean use par("col").

font
font for text. Can be a vector. NA values (the default) mean use par("font").

... Further graphical parameters (see par), including family, las and xpd. (The latter defaults to the figure region unless outer = TRUE, otherwise the device region. It can only be increased.)

**Details**

The user coordinates in the outer margins always range from zero to one, and are not affected by the user coordinates in the figure region(s) — R differs here from other implementations of S.

All of the named arguments can be vectors, and recycling will take place to plot as many strings as the longest of the vector arguments.

Note that a vector adj has a different meaning from text. adj = 0.5 will centre the string, but for outer = TRUE on the device region rather than the plot region.

Parameter las will determine the orientation of the string(s). For strings plotted perpendicular to the axis the default justification is to place the end of the string nearest the axis on the specified line. (Note that this differs from S, which uses srt if at is supplied and las if it is not. Parameter srt is ignored in R.)

Note that if the text is to be plotted perpendicular to the axis, adj determines the justification of the string and the position along the axis unless at is specified.

Graphics parameter "ylbias" (see par) determines how the text baseline is placed relative to the nominal line.

**Side Effects**

The given text is written onto the current plot.

**See Also**

title, text, plot, par; plotmath for details on mathematical annotation.

**Examples**

```r
plot(1:10, (-4:5)^2, main = "Parabola Points", xlab = "xlab")
mtext("10 of them")
for(s in 1:4)
  mtext(paste("mtext(..., line= -1, \{side, col, font\} = ", s,
              ", cex = ", (1+s)/2, ", )", line = -1,
              side = s, col = s, font = s, cex = (1+s)/2)
mtext("mtext(..., line= -2")", line = -2)
mtext("mtext(..., line= -2, adj = 0")", line = -2, adj = 0)
##--- log axis :
plot(1:10, exp(1:10), log = "y", main = "log =\"y\"", xlab = "xlab")
for(s in 1:4) mtext(paste("mtext(...,side="s", \")", side = s)
```
pairs

Scatterplot Matrices

Description

A matrix of scatterplots is produced.

Usage

pairs(x, ...)

## S3 method for class 'formula'
pairs(formula, data = NULL, ..., subset,
   na.action = stats::na.pass)

## Default S3 method:
pairs(x, labels, panel = points, ...,
   horInd = 1:nc, verInd = 1:nc,
   lower.panel = panel, upper.panel = panel,
   diag.panel = NULL, text.panel = textPanel,
   label.pos = 0.5 + has.diag/3, line.main = 3,
   cex.labels = NULL, font.labels = 1,
   row1attop = TRUE, gap = 1, log = "",
   horOdd = !row1attop, verOdd = !row1attop)

Arguments

x the coordinates of points given as numeric columns of a matrix or data frame. Logical and factor columns are converted to numeric in the same way that data.matrix does.

formula a formula, such as ~ x + y + z. Each term will give a separate variable in the pairs plot, so terms should be numeric vectors. (A response will be interpreted as another variable, but not treated specially, so it is confusing to use one.)

data a data.frame (or list) from which the variables in formula should be taken.

subset an optional vector specifying a subset of observations to be used for plotting.

na.action a function which indicates what should happen when the data contain NAs. The default is to pass missing values on to the panel functions, but na.action = na.omit will cause cases with missing values in any of the variables to be omitted entirely.

labels the names of the variables.

panel function(x,y,...) which is used to plot the contents of each panel of the display.

... arguments to be passed to or from methods.

Also, graphical parameters can be given as can arguments to plot such as main. par("oma") will be set appropriately unless specified.

horInd, verInd The (numerical) indices of the variables to be plotted on the horizontal and vertical axes respectively.
pairs

lower.panel, upper.panel
separate panel functions (or NULL) to be used below and above the diagonal respectively.

diag.panel
optional function(x,...) to be applied on the diagonals.
text.panel
optional function(x,y,labels,cex,font,...) to be applied on the diagonals.

label.pos
y position of labels in the text panel.

line.main
if main is specified, line.main gives the line argument to mtext() which draws the title. You may want to specify oma when changing line.main.

cex.labels, font.labels
graphics parameters for the text panel.

row1atop
logical. Should the layout be matrix-like with row 1 at the top, or graph-like with row 1 at the bottom? The latter (non default) leads to a basically symmetric scatterplot matrix.

gap
distance between subplots, in margin lines.

log
a character string indicating if logarithmic axes are to be used. see plot.default or a numeric vector of indices specifying the indices of those variables where logarithmic axes should be used for both x and y. log = "xy" specifies logarithmic axes for all variables.

horOdd, verOdd logical (or integer) determining how the horizontal and vertical axis labeling happens. If true, the axis labelling starts at the first (from top left) row or column, respectively.

Details

The $ij$th scatterplot contains $x[,i]$ plotted against $x[,j]$. The scatterplot can be customised by setting panel functions to appear as something completely different. The off-diagonal panel functions are passed the appropriate columns of $x$ as $x$ and $y$: the diagonal panel function (if any) is passed a single column, and the text.panel function is passed a single $(x,y)$ location and the column name. Setting some of these panel functions to NULL is equivalent to not drawing anything there.

The graphical parameters pch and col can be used to specify a vector of plotting symbols and colors to be used in the plots.

The graphical parameter oma will be set by pairs.default unless supplied as an argument.

A panel function should not attempt to start a new plot, but just plot within a given coordinate system: thus plot and boxplot are not panel functions.

By default, missing values are passed to the panel functions and will often be ignored within a panel. However, for the formula method and na.action = na.omit, all cases which contain a missing values for any of the variables are omitted completely (including when the scales are selected).

Arguments horInd and verInd were introduced in R 3.2.0. If given the same value they can be used to select or re-order variables: with different ranges of consecutive values they can be used to plot rectangular windows of a full pairs plot; in the latter case ‘diagonal’ refers to the diagonal of the full plot.

Examples

```r
pairs(iris[1:4], main = "Anderson's Iris Data -- 3 species",
     pch = 21, bg = c("red", "green3", "blue")[unclass(iris$Species)])

## formula method, "graph" layout (row 1 at bottom):
pairs(~ Fertility + Education + Catholic, data = swiss, rowlattop=FALSE,
     subset = Education < 20, main = "Swiss data, Education < 20")
pairs(USJudgeRatings, gap=1/10) # (gap: not wasting plotting area)
## show only lower triangle (and suppress labeling for whatever reason):
pairs(USJudgeRatings, text.panel = NULL, upper.panel = NULL)

## put histograms on the diagonal
panel.hist <- function(x, ...) {
    usr <- par("usr"); on.exit(par(usr))
    par(usr = c(usr[1:2], 0, 1.5 )
    h <- hist(x, plot = FALSE)
    breaks <- h$breaks; nB <- length(breaks)
    y <- h$counts; y <- y/max(y)
    rect(breaks[-nB], 0, breaks[-1], y, col = "cyan", ...)
}
pairs(USJudgeRatings[1:5], panel = panel.smooth,
     cex = 1.5, pch = 24, bg = "light blue", horOdd=TRUE,
     diag.panel = panel.hist, cex.labels = 2, font.labels = 2)

## put (absolute) correlations on the upper panels,
## with size proportional to the correlations.
panel.cor <- function(x, y, digits = 2, prefix = ",", cex.cor, ...) {
    us <- par("usr"); on.exit(par(us))
    par(us = c(0, 1, 0, 1))
    r <- abs(cor(x, y))
    txt <- format(c(r, 0.123456789), digits = digits)[1]
    txt <- paste0(prefix, txt)
    if(missing(cex.cor)) cex.cor <- 0.85/strwidth(txt)
    text(0.5, 0.5, txt, cex = cex.cor * r)
}
pairs(USJudgeRatings, lower.panel = panel.smooth, upper.panel = panel.cor,
     gap=0, rowlattop=FALSE)
pairs(iris[-5], log = "xy") # plot all variables on log scale
pairs(iris, log = 1:4, # log the first four
     main = "Lengths and Widths in [log]", line.main=1.5, oma=c(2,2,3,2))
```

panel.smooth

*Simple Panel Plot*
Description

An example of a simple useful panel function to be used as argument in e.g., `coplot` or `pairs`.

Usage

```r
panel.smooth(x, y, col = par("col"), bg = NA, pch = par("pch"),
             cex = 1, col.smooth = 2, span = 2/3, iter = 3,
             ...)```

Arguments

- `x, y`: numeric vectors of the same length
- `col, bg, pch, cex`: numeric or character codes for the color(s), point type and size of points; see also `par`.
- `col.smooth`: color to be used by `lines` for drawing the smooths.
- `span`: smoothing parameter $f$ for `lowess`, see there.
- `iter`: number of robustness iterations for `lowess`.
- `...`: further arguments to `lines`.

See Also

coplot and pairs where `panel.smooth` is typically used; lowess which does the smoothing.

Examples

```r
pairs(swiss, panel = panel.smooth, pch = ".") # emphasize the smooths
pairs(swiss, panel = panel.smooth, lwd = 2, cex = 1.5, col = 4) # hmm...
```

par

Set or Query Graphical Parameters

Description

`par` can be used to set or query graphical parameters. Parameters can be set by specifying them as arguments to `par` in `tag = value` form, or by passing them as a list of tagged values.

Usage

```r
par(..., no.readonly = FALSE)
```

Arguments

- `...`: arguments in `tag = value` form, or a list of tagged values. The tags must come from the names of graphical parameters described in the ‘Graphical Parameters’ section.
- `no.readonly`: logical; if TRUE and there are no other arguments, only parameters are returned which can be set by a subsequent `par()` call on the same device.
Details

Each device has its own set of graphical parameters. If the current device is the null device, `par` will open a new device before querying/setting parameters. (What device is controlled by `options("device")`.)

Parameters are queried by giving one or more character vectors of parameter names to `par`.

`par()` (no arguments) or `par(no.readonly = TRUE)` is used to get all the graphical parameters (as a named list). Their names are currently taken from the unexported variable `graphics:::.Pars`.

**R.O.** indicates read-only arguments: These may only be used in queries and cannot be set. ("cin", "cra", "csi", "cxy", "din" and "page" are always read-only.)

Several parameters can only be set by a call to `par()`:

- "ask",
- "fig", "fin",
- "lheight",
- "mai", "mar", "mex", "mfcol", "mfrow", "mfg",
- "new",
- "oma", "omd", "omi",
- "pin", "plt", "ps", "pty",
- "usr",
- "xlog", "ylog",
- "ylbias"

The remaining parameters can also be set as arguments (often via `...`) to high-level plot functions such as `plot.default`, `plot.window`, `points`, `lines`, `abline`, `axis`, `title`, `text`, `mtext`, `segments`, `symbols`, `arrows`, `polygon`, `rect`, `box`, `contour`, `filled.contour` and `image`. Such settings will be active during the execution of the function, only. However, see the comments on `bg`, `cex`, `col`, `lty`, `lwd` and `pch` which may be taken as arguments to certain plot functions rather than as graphical parameters.

The meaning of ‘character size’ is not well-defined: this is set up for the device taking `pointsize` into account but often not the actual font family in use. Internally the corresponding pars (cra, cin, cxy and csi) are used only to set the inter-line spacing used to convert `mar` and `oma` to physical margins. (The same inter-line spacing multiplied by `lheight` is used for multi-line strings in `text` and `strheight`.)

Note that graphical parameters are suggestions: plotting functions and devices need not make use of them (and this is particularly true of non-default methods for e.g. `plot`).

Value

When parameters are set, their previous values are returned in an invisible named list. Such a list can be passed as an argument to `par` to restore the parameter values. Use `par(no.readonly = TRUE)` for the full list of parameters that can be restored. However, restoring all of these is not wise: see the ‘Note’ section.

When just one parameter is queried, the value of that parameter is returned as (atomic) vector. When two or more parameters are queried, their values are returned in a list, with the list names giving the parameters.

Note the inconsistency: setting one parameter returns a list, but querying one parameter returns a vector.
**Graphical Parameters**

- **adj** The value of adj determines the way in which text strings are justified in `text`, `mtext` and `title`. A value of 0 produces left-justified text, 0.5 (the default) centered text and 1 right-justified text. (Any value in [0, 1] is allowed, and on most devices values outside that interval will also work.)

  Note that the adj argument of `text` also allows adj = c(x, y) for different adjustment in x- and y-directions. Note that whereas for `text` it refers to positioning of text about a point, for `mtext` and `title` it controls placement within the plot or device region.

- **ann** If set to FALSE, high-level plotting functions calling `plot.default` do not annotate the plots they produce with axis titles and overall titles. The default is to do annotation.

- **ask** logical. If TRUE (and the R session is interactive) the user is asked for input, before a new figure is drawn. As this applies to the device, it also affects output by packages `grid` and `lattice`. It can be set even on non-screen devices but may have no effect there.

  This not really a graphics parameter, and its use is deprecated in favour of `devAskNewPage`.

- **bg** The color to be used for the background of the device region. When called from `par()` it also sets new = FALSE. See section ‘Color Specification’ for suitable values. For many devices the initial value is set from the bg argument of the device, and for the rest it is normally "white".

  Note that some graphics functions such as `plot.default` and `points` have an argument of this name with a different meaning.

- **bty** A character string which determined the type of box which is drawn about plots. If bty is one of "o" (the default), "l", "7", "c", "u", or "]\) the resulting box resembles the corresponding upper case letter. A value of "n" suppresses the box.

- **cex** A numerical value giving the amount by which plotting text and symbols should be magnified relative to the default. This starts as 1 when a device is opened, and is reset when the layout is changed, e.g. by setting `mfrow`.

  Note that some graphics functions such as `plot.default` have an argument of this name which multiplies this graphical parameter, and some functions such as `points` and `text` accept a vector of values which are recycled.

- **cex.axis** The magnification to be used for axis annotation relative to the current setting of cex.

- **cex.lab** The magnification to be used for x and y labels relative to the current setting of cex.

- **cex.main** The magnification to be used for main titles relative to the current setting of cex.

- **cex.sub** The magnification to be used for sub-titles relative to the current setting of cex.

- **cin** R.O.; character size (width, height) in inches. These are the same measurements as cra, expressed in different units.

- **col** A specification for the default plotting color. See section ‘Color Specification’.

  Some functions such as `lines` and `text` accept a vector of values which are recycled and may be interpreted slightly differently.

- **col.axis** The color to be used for axis annotation. Defaults to "black".

- **col.lab** The color to be used for x and y labels. Defaults to "black".

- **col.main** The color to be used for plot main titles. Defaults to "black".

- **col.sub** The color to be used for plot sub-titles. Defaults to "black".

- **cra** R.O.; size of default character (width, height) in ‘rasters’ (pixels). Some devices have no concept of pixels and so assume an arbitrary pixel size, usually 1/72 inch. These are the same measurements as cin, expressed in different units.

- **crt** A numerical value specifying (in degrees) how single characters should be rotated. It is unwise to expect values other than multiples of 90 to work. Compare with srt which does string rotation.
par

**csi** *R.O.*: height of (default-sized) characters in inches. The same as `par("cin")[2].

**cxy** *R.O.*: size of default character (width,height) in user coordinate units. `par("cxy")` is `par("cin")/par("pin")` scaled to user coordinates. Note that `c(strwidth(ch),strheight(ch))` for a given string `ch` is usually much more precise.

**din** *R.O.*: the device dimensions, (width,height), in inches. See also `dev.size`, which is updated immediately when an on-screen device windows is re-sized.

**err** (*Unimplemented_; R is silent when points outside the plot region are *not* plotted.) The degree of error reporting desired.

**family** The name of a font family for drawing text. The maximum allowed length is 200 bytes. This name gets mapped by each graphics device to a device-specific font description. The default value is "" which means that the default device fonts will be used (and what those are should be listed on the help page for the device). Standard values are "serif", "sans" and "mono", and the Hershey font families are also available. (Devices may define others, and some devices will ignore this setting completely. Names starting with "Hershey" are treated specially and should only be used for the built-in Hershey font families.) This can be specified inline for `text`.

**fg** The color to be used for the foreground of plots. This is the default color used for things like axes and boxes around plots. When called from `par()` this also sets parameter `col` to the same value. See section ‘Color Specification’. A few devices have an argument to set the initial value, which is otherwise "black".

**fig** A numerical vector of the form `c(x1,x2,y1,y2)` which gives the (NDC) coordinates of the figure region in the display region of the device. If you set this, unlike S, you start a new plot, so to add to an existing plot use `new = TRUE` as well.

**fin** The figure region dimensions, (width,height), in inches. If you set this, unlike S, you start a new plot.

**font** An integer which specifies which font to use for text. If possible, device drivers arrange so that 1 corresponds to plain text (the default), 2 to bold face, 3 to italic and 4 to bold italic. Also, font 5 is expected to be the symbol font, in Adobe symbol encoding. On some devices font families can be selected by `family` to choose different sets of 5 fonts.

**font.axis** The font to be used for axis annotation.

**font.lab** The font to be used for x and y labels.

**font.main** The font to be used for plot main titles.

**font.sub** The font to be used for plot sub-titles.

**lab** A numerical vector of the form `c(x,y,len)` which modifies the default way that axes are annotated. The values of `x` and `y` give the (approximate) number of tickmarks on the x and y axes and `len` specifies the label length. The default is `c(5,5,7)`. Note that this only affects the way the parameters `xaxp` and `yaxp` are set when the user coordinate system is set up, and is not consulted when axes are drawn. `len` is *unimplemented* in R.

**las** numeric in {0,1,2,3}; the style of axis labels.

- **0**: always parallel to the axis [*default*].
- **1**: always horizontal,
- **2**: always perpendicular to the axis,
- **3**: always vertical.

Also supported by `mtext`. Note that string/character rotation via argument srt to `par` does *not* affect the axis labels.

**lend** The line end style. This can be specified as an integer or string:

- **0** and "round" mean rounded line caps [*default*];
1 and "butt" mean butt line caps;
2 and "square" mean square line caps.

lheight The line height multiplier. The height of a line of text (used to vertically space multi-line
text) is found by multiplying the character height both by the current character expansion and
by the line height multiplier. Default value is 1. Used in text and strheight.

ljoin The line join style. This can be specified as an integer or string:
0 and "round" mean rounded line joins [default];
1 and "mitre" mean mitred line joins;
2 and "bevel" mean bevelled line joins.

lmitre The line mitre limit. This controls when mitred line joins are automatically converted into
bevelled line joins. The value must be larger than 1 and the default is 10. Not all devices will
honour this setting.

lty The line type. Line types can either be specified as an integer (0=blank, 1=solid (default),
2=dashed, 3=dotted, 4=dotdash, 5=longdash, 6=twodash) or as one of the character strings
"blank", "solid", "dashed", "dotted", "dotdash", "longdash", or "twodash", where
"blank" uses ‘invisible lines’ (i.e., does not draw them).
Alternatively, a string of up to 8 characters (from c(1:9,"A":"F") may be given, giving the
length of line segments which are alternatively drawn and skipped. See section ‘Line Type
Specification’.
Functions such as lines and segments accept a vector of values which are recycled.

lwd The line width, a positive number, defaulting to 1. The interpretation is device-specific, and
some devices do not implement line widths less than one. (See the help on the device for
details of the interpretation.)
Functions such as lines and segments accept a vector of values which are recycled: in such
uses lines corresponding to values NA or NaN are omitted. The interpretation of 0 is device-
specific.

mai A numerical vector of the form c(bottom,left,top,right) which gives the margin size
specified in inches.

mar A numerical vector of the form c(bottom,left,top,right) which gives the number of lines
of margin to be specified on the four sides of the plot. The default is c(5,4,4,2) + 0.1.
mex \textit{mex} is a character size expansion factor which is used to describe coordinates in the margins of plots. Note that this does not change the font size, rather specifies the size of font (as a multiple of \textit{csi}) used to convert between \textit{mar} and \textit{mai}, and between \textit{oma} and \textit{omi}.

This starts as 1 when the device is opened, and is reset when the layout is changed (alongside resetting \textit{cex}).

\textit{mfcol}, \textit{mfrow} A vector of the form \(c(nr, nc)\). Subsequent figures will be drawn in an \(nr\)-by-\(nc\) array on the device by \textit{columns} (\textit{mfcol}), or \textit{rows} (\textit{mfrow}), respectively.

In a layout with exactly two rows and columns the base value of \textit{"cex"} is reduced by a factor of 0.83: if there are three or more of either rows or columns, the reduction factor is 0.66.

Setting a layout resets the base value of \textit{cex} and that of \textit{mex} to 1.

If either of these is queried it will give the current layout, so querying cannot tell you the order in which the array will be filled.

Consider the alternatives, \texttt{layout} and \texttt{split.screen}.

\textit{mfg} A numerical vector of the form \(c(i, j)\) where \(i\) and \(j\) indicate which figure in an array of figures is to be drawn next (if setting) or is being drawn (if enquiring). The array must already have been set by \textit{mfcol} or \textit{mfrow}.

For compatibility with S, the form \(c(i, j,nr, nc)\) is also accepted, when \(nr\) and \(nc\) should be the current number of rows and number of columns. Mismatches will be ignored, with a warning.

\textit{mgp} The margin line (in \textit{mex} units) for the axis title, axis labels and axis line. Note that \textit{mgp}[1] affects \texttt{title} whereas \textit{mgp}[2:3] affect \texttt{axis}. The default is \(c(3, 1, 0)\).

\textit{mkh} The height in inches of symbols to be drawn when the value of \textit{pch} is an integer. \textit{Completely ignored in R}.

\textit{new} logical, defaulting to \texttt{FALSE}. If set to \texttt{TRUE}, the next high-level plotting command (actually \texttt{plot.new}) should not clean the frame before drawing \textit{as if it were on a new device}. It is an error (ignored with a warning) to try to use \texttt{new = TRUE} on a device that does not currently contain a high-level plot.

\textit{oma} A vector of the form \(c(\text{bottom}, \text{left}, \text{top}, \text{right})\) giving the size of the outer margins in lines of text.

\textit{omd} A vector of the form \(c(x1, x2, y1, y2)\) giving the region \textit{inside} outer margins in \texttt{NDC} (= normalized device coordinates), i.e., as a fraction (in \([0, 1]\)) of the device region.
omi A vector of the form \(c(\text{bottom}, \text{left}, \text{top}, \text{right})\) giving the size of the outer margins in inches.

page \textbf{R.O.} A boolean value indicating whether the next call to \texttt{plot.new} is going to start a new page. This value may be \texttt{FALSE} if there are multiple figures on the page.

pch Either an integer specifying a symbol or a single character to be used as the default in plotting points. See \texttt{points} for possible values and their interpretation. Note that only integers and single-character strings can be set as a graphics parameter (and not \texttt{NA} nor \texttt{NULL}). Some functions such as \texttt{points} accept a vector of values which are recycled.

pin The current plot dimensions, \((\text{width}, \text{height})\), in inches.

plt A vector of the form \(c(x_1, x_2, y_1, y_2)\) giving the coordinates of the plot region as fractions of the current figure region.

ps integer; the point size of text (but not symbols). Unlike the \texttt{pointsize} argument of most devices, this does not change the relationship between \texttt{mar} and \texttt{mai} (nor \texttt{oma} and \texttt{omi}).

What is meant by ‘point size’ is device-specific, but most devices mean a multiple of 1bp, that is 1/72 of an inch.

pty A character specifying the type of plot region to be used; “s” generates a square plotting region and “m” generates the maximal plotting region.

smo (\textit{Unimplemented}) a value which indicates how smooth circles and circular arcs should be.

srt The string rotation in degrees. See the comment about \texttt{crt}. Only supported by \texttt{text}.

tck The length of tick marks as a fraction of the smaller of the width or height of the plotting region. If \(\text{tck} \geq 0.5\) it is interpreted as a fraction of the relevant side, so if \(\text{tck} = 1\) grid lines are drawn. The default setting (\(\text{tck} = \text{NA}\)) is to use \(\text{tck} = -0.5\).

tcl The length of tick marks as a fraction of the height of a line of text. The default value is \(-0.5\); setting \(\text{tcl} = \text{NA}\) sets \(\text{tck} = -0.01\) which is S’ default.

usr A vector of the form \(c(x_1, x_2, y_1, y_2)\) giving the extremes of the user coordinates of the plotting region. When a logarithmic scale is in use (i.e., \texttt{par(“xlog”)}) is true, see below), then the x-limits will be \(10^{\text{par(“usr”)}[1:2]}\). Similarly for the y-axis.

xaxp A vector of the form \(c(x_1, x_2, n)\) giving the coordinates of the extreme tick marks and the number of intervals between tick-marks when \texttt{par(“xlog”)}) is false. Otherwise, when \texttt{log} coordinates are active, the three values have a different meaning: For a small range, \(n\) is negative, and the ticks are as in the linear case, otherwise, \(n\) is in \(1:3\), specifying a case number, and \(x_1\) and \(x_2\) are the lowest and highest power of 10 inside the user coordinates, \(10^n \text{par(“usr”)}[1:2]\). (The “usr” coordinates are log10-transformed here!)

- \(n = 1\) will produce tick marks at \(10^j\) for integer \(j\),
- \(n = 2\) gives marks \(k10^j\) with \(k \in \{1, 5\}\),
- \(n = 3\) gives marks \(k10^j\) with \(k \in \{1, 2, 5\}\).

See \texttt{axTicks()} for a pure \texttt{R} implementation of this. This parameter is reset when a user coordinate system is set up, for example by starting a new page or by calling \texttt{plot.window} or setting \texttt{par(“usr”)}. \(n\) is taken from \texttt{par(“lab”)}. It affects the default behaviour of subsequent calls to \texttt{axis} for sides 1 or 3. It is only relevant to default numeric axis systems, and not for example to dates.

xaxs The style of axis interval calculation to be used for the x-axis. Possible values are “r”, “i”, “e”, “s”, “d”. The styles are generally controlled by the range of data or xlim, if given. Style “r” (regular) first extends the data range by 4 percent at each end and then finds an axis with pretty labels that fits within the extended range. Style “i” (internal) just finds an axis with pretty labels that fits within the original data range. Style “s” (standard) finds an axis with pretty labels within which the original data range fits.
Style "e" (extended) is like style "s", except that it is also ensures that there is room for plotting symbols within the bounding box.

Style "d" (direct) specifies that the current axis should be used on subsequent plots.

(Only "r" and "i" styles have been implemented in R.)

xaxt A character which specifies the x axis type. Specifying "n" suppresses plotting of the axis. The standard value is "s": for compatibility with S values "1" and "t" are accepted but are equivalent to "s": any value other than "n" implies plotting.

xlog A logical value (see log in plot.default). If TRUE, a logarithmic scale is in use (e.g., after plot(*,log = "x")). For a new device, it defaults to FALSE, i.e., linear scale.

xpd A logical value or NA. If FALSE, all plotting is clipped to the plot region, if TRUE, all plotting is clipped to the figure region, and if NA, all plotting is clipped to the device region. See also clip.

yaxp A vector of the form \(c(y_1, y_2, n)\) giving the coordinates of the extreme tick marks and the number of intervals between tick-marks unless for log coordinates, see xaxp above.

yaxs The style of axis interval calculation to be used for the y-axis. See xaxs above.

yaxt A character which specifies the y axis type. Specifying "n" suppresses plotting.

ylbias A positive real value used in the positioning of text in the margins by axis and mtext. The default is in principle device-specific, but currently 0.2 for all of R's own devices. Set this to 0.2 for compatibility with R < 2.14.0 on x11 and windows() devices.

ylog A logical value; see xlog above.

Color Specification

Colors can be specified in several different ways. The simplest way is with a character string giving the color name (e.g., "red"). A list of the possible colors can be obtained with the function colors. Alternatively, colors can be specified directly in terms of their RGB components with a string of the form "#RRGGBB" where each of the pairs RR, GG, BB consist of two hexadecimal digits giving a value in the range 00 to FF. Colors can also be specified by giving an index into a small table of colors, the palette: indices wrap round so with the default palette of size 8, 10 is the same as 2. This provides compatibility with S. Index 0 corresponds to the background color. Note that the palette (apart from 0 which is per-device) is a per-session setting.

Negative integer colours are errors.

Additionally, "transparent" is transparent, useful for filled areas (such as the background!), and just invisible for things like lines or text. In most circumstances (integer) NA is equivalent to "transparent" (but not for text and mtext).

Semi-transparent colors are available for use on devices that support them. The functions rgb, hsv, hcl, gray and rainbow provide additional ways of generating colors.

Line Type Specification

Line types can either be specified by giving an index into a small built-in table of line types (1 = solid, 2 = dashed, etc, see 1ty above) or directly as the lengths of on/off stretches of line. This is done with a string of an even number (up to eight) of characters, namely non-zero (hexadecimal) digits which give the lengths in consecutive positions in the string. For example, the string "33" specifies three units on followed by three off and "3313" specifies three units on followed by three off followed by one on and finally three off. The ‘units’ here are (on most devices) proportional to lwd, and with lwd = 1 are in pixels or points or 1/96 inch.

The five standard dash-dot line types (1ty = 2:6) correspond to c("44","13","1343","73","2262").

Note that NA is not a valid value for 1ty.
Note

The effect of restoring all the (settable) graphics parameters as in the examples is hard to predict if the device has been resized. Several of them are attempting to set the same things in different ways, and those last in the alphabet will win. In particular, the settings of mai, mar, pin, plt and pty interact, as do the outer margin settings, the figure layout and figure region size.

Examples

```r
op <- par(mfrow = c(2, 2), # 2 x 2 pictures on one plot
       pty = "s")       # square plotting region,
       # independent of device size

## At end of plotting, reset to previous settings:
par(op)

## Alternatively,
op <- par(no.readonly = TRUE) # the whole list of settable par's.
## do lots of plotting and par(.) calls, then reset:
par(op)
## Note this is not in general good practice

par("ylog") # FALSE
plot(1 : 12, log = "y")
par("ylog") # TRUE

plot(1:2, xaxs = "i") # 'inner axis' w/o extra space
par(c("usr", "xaxp"))

persp # Perspective Plots

Description
This function draws perspective plots of a surface over the x–y plane. persp is a generic function.

Usage
persp(x, ...)

## Default S3 method:
persp(x = seq(0, 1, length.out = nrow(z)),
y = seq(0, 1, length.out = ncol(z)),
z, xlim = range(x), ylim = range(y),
zlim = range(z, na.rm = TRUE),
xlab = NULL, ylab = NULL, zlab = NULL,
main = NULL, sub = NULL,
theta = 0, phi = 15, r = sqrt(3), d = 1,
scale = TRUE, expand = 1,
col = "white", border = NULL, ltheta = -135, lphi = 0,
shade = NA, box = TRUE, axes = TRUE, nticks = 5,
ticktype = "simple", ...)
Arguments

x, y  
locations of grid lines at which the values in z are measured. These must be in ascending order. By default, equally spaced values from 0 to 1 are used. If x is a list, its components x$x and x$y are used for x and y, respectively.

z  
as a matrix containing the values to be plotted (NA s are allowed). Note that x can be used instead of z for convenience.

xlim, ylim, zlim  
x-, y- and z-limits. These should be chosen to cover the range of values of the surface: see ‘Details’.

xlab, ylab, zlab  
titles for the axes. N.B. These must be character strings; expressions are not accepted. Numbers will be coerced to character strings.

main, sub  
main and sub title, as for title.

theta, phi  
angles defining the viewing direction. theta gives the azimuthal direction and phi the colatitude.

r  
the distance of the eyepoint from the centre of the plotting box.

d  
a value which can be used to vary the strength of the perspective transformation. Values of d greater than 1 will lessen the perspective effect and values less and 1 will exaggerate it.

scale  
before viewing the x, y and z coordinates of the points defining the surface are transformed to the interval [0,1]. If scale is TRUE the x, y and z coordinates are transformed separately. If scale is FALSE the coordinates are scaled so that aspect ratios are retained. This is useful for rendering things like DEM information.

expand  
a expansion factor applied to the z coordinates. Often used with 0 < expand < 1 to shrink the plotting box in the z direction.

col  
the color(s) of the surface facets. Transparent colours are ignored. This is recycled to the \((nx - 1)(ny - 1)\) facets.

border  
the color of the line drawn around the surface facets. The default, NULL, corresponds to par("fg"). A value of NA will disable the drawing of borders: this is sometimes useful when the surface is shaded.

ltheta, lphi  
if finite values are specified for ltheta and lphi, the surface is shaded as though it was being illuminated from the direction specified by azimuth ltheta and colatitude lphi.

shade  
the shade at a surface facet is computed as \(((1+d)/2)^shade\), where d is the dot product of a unit vector normal to the facet and a unit vector in the direction of a light source. Values of shade close to one yield shading similar to a point light source model and values close to zero produce no shading. Values in the range 0.5 to 0.75 provide an approximation to daylight illumination.

box  
should the bounding box for the surface be displayed. The default is TRUE.

axes  
should ticks and labels be added to the box. The default is TRUE. If box is FALSE then no ticks or labels are drawn.

ticktype  
character: "simple" draws just an arrow parallel to the axis to indicate direction of increase; "detailed" draws normal ticks as per 2D plots.

nticks  
the (approximate) number of tick marks to draw on the axes. Has no effect if ticktype is "simple".

...  
additional graphical parameters (see par).
Details

The plots are produced by first transforming the \((x,y,z)\) coordinates to the interval \([0,1]\) using the limits supplied or computed from the range of the data. The surface is then viewed by looking at the origin from a direction defined by \(\theta\) and \(\phi\). If \(\theta\) and \(\phi\) are both zero the viewing direction is directly down the negative \(y\) axis. Changing \(\theta\) will vary the azimuth and changing \(\phi\) the colatitude.

There is a hook called "persp" (see \texttt{setHook}) called after the plot is completed, which is used in the testing code to annotate the plot page. The hook function(s) are called with no argument.

Notice that \texttt{persp} interprets the \(z\) matrix as a table of \(f(x[i],y[j])\) values, so that the \(x\) axis corresponds to row number and the \(y\) axis to column number, with column 1 at the bottom, so that with the standard rotation angles, the top left corner of the matrix is displayed at the left hand side, closest to the user.

The sizes and fonts of the axis labels and the annotations for \texttt{ticktype = "detailed"} are controlled by graphics parameters "\texttt{cex.lab}"/"\texttt{font.lab}" and "\texttt{cex.axis}"/"\texttt{font.axis}" respectively.

The bounding box is drawn with edges of faces facing away from the viewer (and hence at the back of the box) with solid lines and other edges dashed and on top of the surface. This (and the plotting of the axes) assumes that the axis limits are chosen so that the surface is within the box, and the function will warn if this is not the case.

Value

\texttt{persp()} returns the \textit{viewing transformation matrix}, say \(VT\), a \(4 \times 4\) matrix suitable for projecting \(3D\) coordinates \((x,y,z)\) into the \(2D\) plane using homogeneous \(4D\) coordinates \((x,y,z,t)\). It can be used to superimpose additional graphical elements on the \(3D\) plot, by \texttt{lines()} or \texttt{points()}, using the function \texttt{trans3d()}.

References

See Also

\texttt{contour} and \texttt{image}; \texttt{trans3d}.

Rotatable \(3D\) plots can be produced by package \texttt{rgl}: other ways to produce static perspective plots are available in packages \texttt{lattice} and \texttt{scatterplot3d}.

# Recode facet z-values into color indices
facetcol <- cut(zfacet, nbcol)
persp(x, y, z, col = color[facetcol], phi = 30, theta = -30)

par(op)
Description

Draw a pie chart.

Usage

```r
pie(x, labels = names(x), edges = 200, radius = 0.8,
clockwise = FALSE, init.angle = if(clockwise) 90 else 0,
density = NULL, angle = 45, col = NULL, border = NULL,
lty = NULL, main = NULL, ...)
```

Arguments

- `x`: a vector of non-negative numerical quantities. The values in `x` are displayed as the areas of pie slices.
- `labels`: one or more expressions or character strings giving names for the slices. Other objects are coerced by `as.graphicsAnnot`. For empty or NA (after coercion to character) labels, no label nor pointing line is drawn.
- `edges`: the circular outline of the pie is approximated by a polygon with this many edges.
- `radius`: the pie is drawn centered in a square box whose sides range from $-1$ to $1$. If the character strings labeling the slices are long it may be necessary to use a smaller radius.
- `clockwise`: logical indicating if slices are drawn clockwise or counter clockwise (i.e., mathematically positive direction), the latter is default.
- `init.angle`: number specifying the starting angle (in degrees) for the slices. Defaults to 0 (i.e., ‘3 o’clock’) unless clockwise is true where `init.angle` defaults to 90 (degrees), (i.e., ‘12 o’clock’).
- `density`: the density of shading lines, in lines per inch. The default value of NULL means that no shading lines are drawn. Non-positive values of density also inhibit the drawing of shading lines.
- `angle`: the slope of shading lines, given as an angle in degrees (counter-clockwise).
- `col`: a vector of colors to be used in filling or shading the slices. If missing a set of 6 pastel colours is used, unless density is specified when `par("fg")` is used.
- `border, lty`: (possibly vectors) arguments passed to `polygon` which draws each slice.
- `main`: an overall title for the plot.
- `...`: `graphical parameters` can be given as arguments to `pie`. They will affect the main title and labels only.

Note

Pie charts are a very bad way of displaying information. The eye is good at judging linear measures and bad at judging relative areas. A bar chart or dot chart is a preferable way of displaying this type of data.

Cleveland (1985), page 264: “Data that can be shown by pie charts always can be shown by a dot chart. This means that judgements of position along a common scale can be made instead of the less accurate angle judgements.” This statement is based on the empirical investigations of Cleveland and McGill as well as investigations by perceptual psychologists.

dotchart.

Examples

require(grDevices)
pie(rep(1, 24), col = rainbow(24), radius = 0.9)
pie.sales <- c(0.12, 0.3, 0.26, 0.16, 0.04, 0.12)
names(pie.sales) <- c("Blueberry", "Cherry", "Apple", "Boston Cream", "Other", "Vanilla Cream")
pie(pie.sales) # default colours
pie(pie.sales, col = c("purple", "violetred1", "green3", "cornsilk", "cyan", "white"))
pie(pie.sales, col = gray(seq(0.4, 1.0, length = 6)))
pie(pie.sales, density = 10, angle = 15 + 10 * 1:6)
pie(pie.sales, clockwise = TRUE, main = "pie(*, clockwise = TRUE")
segments(0, 0, 0, 1, col = "red", lwd = 2)
text(0, 1, "init.angle = 90", col = "red")
n <- 200
pie(rep(1, n), labels = ", col = rainbow(n), border = NA,
     main = "pie(*, labels="", col=rainbow(n), border=NA,...")

## Another case showing pie() is rather fun than science:
## (original by FinalBackwardsGlance on http://imgur.com/gallery/wWrpu4X)
pie(c(Sky = 78, "Sunny side of pyramid" = 17, "Shady side of pyramid" = 5),
    init.angle = 315, col = c("deepskyblue", "yellow", "yellow3"), border = FALSE)

plot.data.frame  Plot Method for Data Frames

Description

plot.data.frame, a method for the plot generic. It is designed for a quick look at numeric data frames.

Usage

## S3 method for class 'data.frame'
plot(x, ...)

Arguments

x  object of class data.frame.
...

further arguments to stripchart, plot.default or pairs.
Details

This is intended for data frames with numeric columns. For more than two columns it first calls `data.matrix` to convert the data frame to a numeric matrix and then calls `pairs` to produce a scatterplot matrix. This can fail and may well be inappropriate: for example numerical conversion of dates will lose their special meaning and a warning will be given.

For a two-column data frame it plots the second column against the first by the most appropriate method for the first column.

For a single numeric column it uses `stripchart`, and for other single-column data frames tries to find a plot method for the single column.

See Also

data.frame

Examples

```r
plot(OrchardSprays[1], method = "jitter")
plot(OrchardSprays[, c(4,1)])
plot(OrchardSprays)

plot(iris)
plot(iris[5:4])
plot(women)
```

Description

Draw a scatter plot with decorations such as axes and titles in the active graphics window.

Usage

```
## Default S3 method:
plot(x, y = NULL, type = "p", xlim = NULL, ylim = NULL,
     log = "", main = NULL, sub = NULL, xlab = NULL, ylab = NULL,
     ann = par("ann"), axes = TRUE, frame.plot = axes,
     panel.first = NULL, panel.last = NULL, asp = NA,
     xgap.axis = NA, ygap.axis = NA,
     ...)```

Arguments

- `x, y` the x and y arguments provide the x and y coordinates for the plot. Any reasonable way of defining the coordinates is acceptable. See the function `xy.coords` for details. If supplied separately, they must be of the same length.
- `type` 1-character string giving the type of plot desired. The following values are possible, for details, see `plot`: "p" for points, "l" for lines, "b" for both points and lines, "c" for empty points joined by lines, "o" for overplotted points and lines, "s" and "S" for stair steps and "h" for histogram-like vertical lines. Finally, "n" does not produce any points or lines.
xlim the x limits (x1, x2) of the plot. Note that x1 > x2 is allowed and leads to a 'reversed axis'. The default value, NULL, indicates that the range of the finite values to be plotted should be used.

ylim the y limits of the plot.

log a character string which contains "x" if the x axis is to be logarithmic, "y" if the y axis is to be logarithmic and "xy" or "yx" if both axes are to be logarithmic.

main a main title for the plot, see also title.

sub a sub title for the plot.

xlab a label for the x axis, defaults to a description of x.

ylab a label for the y axis, defaults to a description of y.

ann a logical value indicating whether the default annotation (title and x and y axis labels) should appear on the plot.

axes a logical value indicating whether both axes should be drawn on the plot. Use graphical parameter "xaxt" or "yaxt" to suppress just one of the axes.

frame.plot a logical indicating whether a box should be drawn around the plot.

panel.first an 'expression' to be evaluated after the plot axes are set up but before any plotting takes place. This can be useful for drawing background grids or scatterplot smooths. Note that this works by lazy evaluation: passing this argument from other plot methods may well not work since it may be evaluated too early.

panel.last an expression to be evaluated after plotting has taken place but before the axes, title and box are added. See the comments about panel.first.

asp the y/x aspect ratio, see plot.window.

xgap.axis, ygap.axis the x/y axis gap factors, passed as gap.axis to the two axis() calls (when axes is true, as per default).

... other graphical parameters (see par and section 'Details' below).

Details

Commonly used graphical parameters are:

col The colors for lines and points. Multiple colors can be specified so that each point can be given its own color. If there are fewer colors than points they are recycled in the standard fashion. Lines will all be plotted in the first colour specified.

col The colors for lines and points. Multiple colors can be specified so that each point can be given its own color. If there are fewer colors than points they are recycled in the standard fashion. Lines will all be plotted in the first colour specified.

col The colors for lines and points. Multiple colors can be specified so that each point can be given its own color. If there are fewer colors than points they are recycled in the standard fashion. Lines will all be plotted in the first colour specified.

bg a vector of background colors for open plot symbols, see points. Note: this is not the same setting as par("bg").

pch a vector of plotting characters or symbols: see points.

cex a numerical vector giving the amount by which plotting characters and symbols should be scaled relative to the default. This works as a multiple of par("cex"). NULL and NA are equivalent to 1.0. Note that this does not affect annotation: see below.

lty a vector of line types, see par.

cex.main, col.lab, font.sub, etc settings for main- and sub-title and axis annotation, see title and par.

lwd a vector of line widths, see par.
plot.default

Note

The presence of panel.first and panel.last is a historical anomaly: default plots do not have 'panels', unlike e.g. pairs plots. For more control, use lower-level plotting functions: plot.default calls in turn some of plot.new, plot.window, plot.xy, axis, box and title, and plots can be built up by calling these individually, or by calling plot(type = "n") and adding further elements.

The plot generic was moved from the graphics package to the base package in R 4.0.0. It is currently re-exported from the graphics namespace to allow packages importing it from there to continue working, but this may change in future versions of R.

y <- exp(-.5*lx^2)
op <- par(mfrow = c(2,1), mar = par("mar")-c(1,0,2,0), mgp = c(2,.7,0))
plot(10^lx, y, log = "xy", type = "l", col = "purple",
     main = "Log-Log plot", ylab = yl, xlab = "x")
plot(10^lx, y, log = "xy", type = "o", pch = ".", col = "forestgreen",
     main = "Log-Log plot with custom axes", ylab = yl, xlab = "x",
     axes = FALSE, frame.plot = TRUE)
my.at <- 10^c(1:5)
axis(1, at = my.at, labels = formatC(my.at, format = "fg"))
e.y <- -5:-1 ; at.y <- 10^e.y
axis(2, at = at.y, col.axis = "red", las = 1,
    labels = as.expression(lapply(e.y, function(E) bquote(10^.(E)))))
par(op)

plot.design

Description

Plot univariate effects of one or more factors, typically for a designed experiment as analyzed by aov().

Usage

plot.design(x, y = NULL, fun = mean, data = NULL, ...,
    ylim = NULL, xlab = "Factors", ylab = NULL,
    main = NULL, ask = NULL, xaxt = par("xaxt"),
    axes = TRUE, xtick = FALSE)

Arguments

x either a data frame containing the design factors and optionally the response, or a formula or terms object.
y the response, if not given in x.
fun a function (or name of one) to be applied to each subset. It must return one number for a numeric (vector) input.
data data frame containing the variables referenced by x when that is formula-like.
... graphical parameters such as col, see par.
ylim range of y values, as in plot.default.
xlab x axis label, see title.
ylab y axis label with a `smart` default.
main main title, see title.
ask logical indicating if the user should be asked before a new page is started – in the case of multiple y's.
xaxt character giving the type of x axis.
axes logical indicating if axes should be drawn.
xtick logical indicating if ticks (one per factor) should be drawn on the x axis.

Details

The supplied function will be called once for each level of each factor in the design and the plot will show these summary values. The levels of a particular factor are shown along a vertical line, and the overall value of \( \text{fun()} \) for the response is drawn as a horizontal line.
Note

A big effort was taken to make this closely compatible to the S version. However, `col` (and `fg`) specifications have different effects.

In S this was a method of the `plot` generic function for design objects.

**plot.factor**

Plotting Factor Variables

Description

This functions implements a scatterplot method for factor arguments of the generic plot function. If `y` is missing `barplot` is produced. For numeric `y` a `boxplot` is used, and for a factor `y` a `spineplot` is shown. For any other type of `y` the next plot method is called, normally `plot.default`.
plot.formula

## S3 method for class 'factor'
plot(x, y, legend.text = NULL, ...)

Arguments

- **x, y**: numeric or factor. `y` may be missing.
- **legend.text**: character vector for annotation of `y` axis in the case of a factor `y`: defaults to `levels(y)`. This sets the `yaxlabels` argument of `spineplot`.
- **...**: Further arguments to `barplot`, `boxplot`, `spineplot` or `plot` as appropriate. All of these accept graphical parameters (see `par`) and annotation arguments passed to `title` and `axes = FALSE`. None accept type.

See Also

`plot.default`, `plot.formula`, `barplot`, `boxplot`, `spineplot`.

Examples

```
require(grDevices)

plot(weight ~ group, data = PlantGrowth) # numeric vector ~ factor
plot(cut(weight, 2) ~ group, data = PlantGrowth) # factor ~ factor
## passing "..." to spineplot() eventually:
plot(cut(weight, 3) ~ group, data = PlantGrowth,
    col = hcl(c(0, 120, 240), 50, 70))
plot(PlantGrowth$group, axes = FALSE, main = "no axes") # extremely silly
```

plot.formula

### Formula Notation for Scatterplots

Description

Specify a scatterplot or add points, lines, or text via a formula.

Usage

```
## S3 method for class 'formula'
plot(formula, data = parent.frame(), ..., subset,
    ylab = varnames[response], ask = dev.interactive())

## S3 method for class 'formula'
points(formula, data = parent.frame(), ..., subset)

## S3 method for class 'formula'
lines(formula, data = parent.frame(), ..., subset)

## S3 method for class 'formula'
text(formula, data = parent.frame(), ..., subset)
```

Arguments

- **formula**: a formula, such as y ~ x.
- **data**: a data.frame (or list) from which the variables in formula should be taken. A matrix is converted to a data frame.
- **...**: Arguments to be passed to or from other methods. `horizontal = TRUE` is also accepted.
- **subset**: an optional vector specifying a subset of observations to be used in the fitting process.
- **ylab**: the y label of the plot(s).
- **ask**: logical, see `par`.

Details

For the `lines`, `points` and `text` methods the formula should be of the form y ~ x or y ~ 1 with a left-hand side and a single term on the right-hand side. The `plot` method accepts other forms discussed later in this section.

Both the terms in the formula and the ... arguments are evaluated in data enclosed in `parent.frame()` if data is a list or a data frame. The terms of the formula and those arguments in ... that are of the same length as data are subjected to the subsetting specified in subset. A plot against the running index can be specified as `plot(y ~ 1)`.

If the formula in the `plot` method contains more than one term on the right-hand side, a series of plots is produced of the response against each non-response term.

For the `plot` method the formula can be of the form z + y + z: the variables specified on the right-hand side are collected into a data frame, subsetted if specified, and displayed by `plot.data.frame`.

Missing values are not considered in these methods, and in particular cases with missing values are not removed.

If y is an object (i.e., has a `class` attribute) then `plot.formula` looks for a plot method for that class first. Otherwise, the class of x will determine the type of the plot. For factors this will be a parallel boxplot, and argument `horizontal = TRUE` can be specified (see `boxplot`).

Note that some arguments will need to be protected from premature evaluation by enclosing them in `quote`: currently this is done automatically for `main`, `sub` and `xlab`. For example, it is needed for the `panel.first` and `panel.last` arguments passed to `plot.default`.

Value

These functions are invoked for their side effect of drawing on the active graphics device.

See Also

- `plot.default`, `points`, `lines`, `plot.factor`.

Examples

```r
op <- par(mfrow = c(2,1))
plot(Ozone ~ Wind, data = airquality, pch = as.character(Month))
plot(Ozone ~ Wind, data = airquality, pch = as.character(Month),
     subset = Month != 7)
par(op)

## text.formula() can be very natural:
```
wb <- within(warpbreaks,
    time <- seq_along(breaks); W.T <- wool:tension)
plot(breaks ~ time, data = wb, type = "b")
text(breaks ~ time, data = wb, label = W.T, col = 1+as.integer(wool))

plot.histogram

## S3 method for class 'histogram'
plot(x, freq = equidist, density = NULL, angle = 45,
    col = NULL, border = par("fg"), lty = NULL,
    main = paste("Histogram of",
    paste(x$xname, collapse = "\n")),
    sub = NULL, xlab = x$xname, ylab,
    xlim = range(x$breaks), ylim = NULL,
    axes = TRUE, labels = FALSE, add = FALSE,
    ann = TRUE, ...)

## S3 method for class 'histogram'
lines(x, ...)
plot.raster

Details

lines.histogram(*) is the same as plot.histogram(*, add = TRUE).

See Also

hist, stem, density.

Examples

(wwt <- hist(women$weight, nclass = 7, plot = FALSE))
plot(wwt, labels = TRUE) # default main & xlab using wwt$xname
plot(wwt, border = "dark blue", col = "light blue",
     main = "Histogram of 15 women's weights", xlab = "weight [pounds]")

## Fake "lines" example, using non-default labels:
w2 <- wwt; w2$counts <- w2$counts - 1
lines(w2, col = "Midnight Blue", labels = ifelse(w2$counts, "> 1", "1"))

plot.raster

Plotting Raster Images

Description

This function implements a plot method for raster images.

Usage

## S3 method for class 'raster'
plot(x, y,
     xlim = c(0, ncol(x)), ylim = c(0, nrow(x)),
     xaxs = "i", yaxs = "i",
     asp = 1, add = FALSE, ...)

Arguments

x, y      raster. y will be ignored.
xlim, ylim Limits on the plot region (default from dimensions of the raster).
xaxs, yaxs Axis interval calculation style (default means that raster fills plot region).
asp       Aspect ratio (default retains aspect ratio of the raster).
add       Logical indicating whether to simply add raster to an existing plot.
...       Further arguments to the rasterImage function.

See Also

plot.default, rasterImage.
Examples

```r
require(grDevices)

r <- as.raster(c(0.5, 1, 0.5))
plot(r)
# additional arguments to rasterImage()
plot(r, interpolate=FALSE)
# distort
plot(r, asp=NA)
# fill page
op <- par(mar=rep(0, 4))
plot(r, asp=NA)
par(op)
# normal annotations work
plot(r, asp=NA)
box()
title(main="This is my raster")
# add to existing plot
plot()
plot(r, add=TRUE)
```

---

**plot.table**

*Plot Methods for table Objects*

**Description**

This is a method of the generic `plot` function for (contingency) `table` objects. Whereas for two- and more dimensional tables, a `mosaicplot` is drawn, one-dimensional ones are plotted as bars.

**Usage**

```r
## S3 method for class 'table'
plot(x, type = "h", ylim = c(0, max(x)), lwd = 2,
     xlab = NULL, ylab = NULL, frame.plot = is.num, ...)
## S3 method for class 'table'
points(x, y = NULL, type = "h", lwd = 2, ...)
## S3 method for class 'table'
lines(x, y = NULL, type = "h", lwd = 2, ...)
```

**Arguments**

- `x`  
  A `table` (like) object.
- `y`  
  Must be `NULL`: there to protect against incorrect calls.
- `type`  
  Plotting type.
- `ylim`  
  Range of y-axis.
- `lwd`  
  Line width for bars when `type = "h"` is used in the 1D case.
- `xlab`, `ylab`  
  X- and y-axis labels.
- `frame.plot`  
  Logical indicating if a frame (`box`) should be drawn in the 1D case. Defaults to true when `x` has `dimnames` coerce-able to numbers.
- `...`  
  Further graphical arguments, see `plot.default`. `axes = FALSE` is accepted.
plot.window

Set up World Coordinates for Graphics Window

Description

This function sets up the world coordinate system for a graphics window. It is called by higher level functions such as plot.default (after plot.new).

Usage

plot.window(xlim, ylim, log = "", asp = NA, ...)

Arguments

xlim, ylim numeric vectors of length 2, giving the x and y coordinates ranges.

log character; indicating which axes should be in log scale.

asp numeric, giving the aspect ratio y/x, see ‘Details’.

... further graphical parameters as in par. The relevant ones are xaxs, yaxs and lab.

Details

asp: If asp is a finite positive value then the window is set up so that one data unit in the y direction is equal in length to asp × one data unit in the x direction.

Note that in this case, par("usr") is no longer determined by, e.g., par("xaxs"), but rather by asp and the device’s aspect ratio. (See what happens if you interactively resize the plot device after running the example below!)

The special case asp == 1 produces plots where distances between points are represented accurately on screen. Values with asp > 1 can be used to produce more accurate maps when using latitude and longitude.

Note that the coordinate ranges will be extended by 4% if the appropriate graphical parameter xaxs or yaxs has value "r" (which is the default).

To reverse an axis, use xlim or ylim of the form c(hi,lo).

The function attempts to produce a plausible set of scales if one or both of xlim and ylim is of length one or the two values given are identical, but it is better to avoid that case.

See Also

plot.factor, the plot method for factors.

Examples

## 1-d tables
(Poisss.tab <- table(N = stats::rpois(200, lambda = 5)))
plot(Poisss.tab, main = "plot(table(rpois(200, lambda = 5)))")

plot(table(state.division))

## 4-D :
plot(Titanic, main = "plot(Titanic, main = *)")
Usually, one should rather use the higher-level functions such as `plot`, `hist`, `image`, ..., instead and refer to their help pages for explanation of the arguments.

A side-effect of the call is to set up the `usr`, `xaxp` and `yaxp` graphical parameters. (It is for the latter two that `lab` is used.)

**See Also**

`xy.coords`, `plot.xy`, `plot.default`

`par` for the graphical parameters mentioned.

**Examples**

```r
##--- An example for the use of 'asp' :
require(stats)  # normally loaded
loc <- cmdscale(eurodist)
rx <- range(x <- loc[,1])
ry <- range(y <- -loc[,2])
plot(x, y, type = "n", asp = 1, xlab = ",", ylab = ",")
abline(h = pretty(rx, 10), v = pretty(ry, 10), col = "lightgray")
text(x, y, labels(eurodist), cex = 0.8)
```

---

**plot.xy**

*Basic Internal Plot Function*

This is *the* internal function that does the basic plotting of points and lines. Usually, one should rather use the higher level functions instead and refer to their help pages for explanation of the arguments.

**Usage**

```r
plot.xy(xy, type, pch = par("pch"), lty = par("lty"),
       col = par("col"), bg = NA,
       cex = 1, lwd = par("lwd"), ...)  
```

**Arguments**

- `xy` A four-element list as results from `xy.coords`.
- `type` 1 character code: see `plot.default`. NULL is accepted as a synonym for "p".
- `pch` character or integer code for kind of points, see `points.default`.
- `lty` line type code, see `lines`.
- `col` color code or name, see `colors`, `palette`. Here NULL means colour 0.
- `bg` background (fill) color for the open plot symbols 21:25: see `points.default`.
- `cex` character expansion.
- `lwd` line width, also used for (non-filled) plot symbols, see `lines` and `points`.
- `...` further graphical parameters such as `xpd`, `lend`, `ljoin` and `lmitre`.
The arguments `pch`, `col`, `bg`, `cex`, `lwd` may be vectors and may be recycled, depending on type: see `points` and `lines` for specifics. In particular note that `lwd` is treated as a vector for points and as a single (first) value for lines.

cex is a numeric factor in addition to `par("cex")` which affects symbols and characters as drawn by type "p", "o", "b" and "c".

See Also

`plot`, `plot.default`, `points`, `lines`.

Examples

```
points.default # to see how it calls "plot.xy(xy.coords(x, y), ...)"
```

## S3 method for class 'default'
points(x, y = NULL, type = "p", 

Arguments

- `x`, `y` coordinate vectors of points to plot.
- `type` character indicating the type of plotting; actually any of the types as in `plot.default`.
- `...` Further graphical parameters may also be supplied as arguments. See ‘Details’.

Details

The coordinates can be passed in a plotting structure (a list with `x` and `y` components), a two-column matrix, a time series, .... See `xy.coords`. If supplied separately, they must be of the same length.

Graphical parameters commonly used are

- `pch` plotting ‘character’, i.e., symbol to use. This can either be a single character or an integer code for one of a set of graphics symbols. The full set of S symbols is available with `pch = 0:18`, see the examples below. (NB: R uses circles instead of the octagons used in S.)
  - Value `pch = "."` (equivalently `pch = 46`) is handled specially. It is a rectangle of side 0.01 inch (scaled by `cex`). In addition, if `cex = 1` (the default), each side is at least one pixel (1/72 inch on the pdf, postscript and xfig devices).
  - For other text symbols, `cex = 1` corresponds to the default fontsize of the device, often specified by an argument `pointsize`. For `pch` in 0:25 the default size is about 75% of the character height (see `par("cin")`).
points

co1  color code or name, see par.
bg   background (fill) color for the open plot symbols given by pch = 21:25.
cex  character (or symbol) expansion: a numerical vector. This works as a multiple of par("cex").
lwd  line width for drawing symbols see par.

Others less commonly used are lty and lwd for types such as "b" and "l".
The graphical parameters pch, co1, bg, cex and lwd can be vectors (which will be recycled as needed) giving a value for each point plotted. If lines are to be plotted (e.g., for type = "b") the first element of lwd is used.

Points whose x, y, pch, co1 or cex value is NA are omitted from the plot.

'pch' values

Values of pch are stored internally as integers. The interpretation is

- NA_integer_: no symbol.
- 0:18: S-compatible vector symbols.
- 19:25: further R vector symbols.
- 26:31: unused (and ignored).
- 32:127: ASCII characters.
- 128:255 native characters only in a single-byte locale and for the symbol font. (128:159 are only used on Windows.)
- -32... Unicode code point (where supported).

Note that unlike S (which uses octagons), symbols 1, 10, 13 and 16 use circles. The filled shapes 15:18 do not include a border.

```
0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25
□ ○ △ □ × ◇ ▽ ● ★ □ ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ● ##  
```

The following R plotting symbols are can be obtained with pch = 19:25: those with 21:25 can be colored and filled with different colors: co1 gives the border color and bg the background color (which is "grey" in the figure)

- pch = 19: solid circle,
- pch = 20: bullet (smaller solid circle, 2/3 the size of 19),
- pch = 21: filled circle,
- pch = 22: filled square,
- pch = 23: filled diamond,
- pch = 24: filled triangle point-up,
- pch = 25: filled triangle point down.

Note that all of these both fill the shape and draw a border. Some care in interpretation is needed when semi-transparent colours are used for both fill and border (and the result might be device-specific and even viewer-specific for pdf).

The difference between pch = 16 and pch = 19 is that the latter uses a border and so is perceptibly larger when lwd is large relative to cex.
Values pch = 26:31 are currently unused and pch = 32:127 give the ASCII characters. In a single-byte locale pch = 128:255 give the corresponding character (if any) in the locale’s character set. Where supported by the OS, negative values specify a Unicode code point, so e.g. -0x2642L is a ‘male sign’ and -0x20ACL is the Euro.

A character string consisting of a single character is converted to an integer: 32:127 for ASCII characters, and usually to the Unicode code point otherwise. (In non-Latin-1 single-byte locales, 128:255 will be used for 8-bit characters.)

If pch supplied is a logical, integer or character NA or an empty character string the point is omitted from the plot.

If pch is NULL or otherwise of length 0, par("pch") is used.

If the symbol font (par(font = 5)) is used, numerical values should be used for pch: the range is c(32:126,160:254) in all locales (but 240 is not defined (used for ‘apple’ on macOS) and 160, Euro, may not be present).

Note

A single-byte encoding may include the characters in pch = 128:255, and if it does, a font may not include all (or even any) of them.

Not all negative numbers are valid as Unicode code points, and no check is done. A display device is likely to use a rectangle for (or omit) Unicode code points which are invalid or for which it does not have a glyph in the font used.

What happens for very small or zero values of cex is device-dependent: symbols or characters may become invisible or they may be plotted at a fixed minimum size. Circles of zero radius will not be plotted.

  for(i in r) try(points(i%%16, i%%16, pch = sign*i, font = font,...))
}
TestChars()
polygon

Description

polygon draws the polygons whose vertices are given in x and y.

Usage

```r
polygon(x, y = NULL, density = NULL, angle = 45,
       border = NULL, col = NA, lty = par("lty"),
       ..., fillOddEven = FALSE)
```

Arguments

- **x, y**: vectors containing the coordinates of the vertices of the polygon.
- **density**: the density of shading lines, in lines per inch. The default value of null means that no shading lines are drawn. A zero value of density means no shading nor filling whereas negative values and NA suppress shading (and so allow color filling).
- **angle**: the slope of shading lines, given as an angle in degrees (counter-clockwise).
- **col**: the color for filling the polygon. The default, NA, is to leave polygons unfilled, unless density is specified. (For back-compatibility, NULL is equivalent to NA.) If density is specified with a positive value this gives the color of the shading lines.
- **border**: the color to draw the border. The default, NULL, means to use `par("fg")`. Use border = NA to omit borders.
  - For compatibility with S, border can also be logical, in which case FALSE is equivalent to NA (borders omitted) and TRUE is equivalent to NULL (use the foreground colour).
- **lty**: the line type to be used, as in `par`.
- **...**: graphical parameters such as xpd, lend, ljoin and lmitre can be given as arguments.
- **fillOddEven**: logical controlling the polygon shading mode: see below for details. Default FALSE.

Details

The coordinates can be passed in a plotting structure (a list with x and y components), a two-column matrix, .... See `xy.coords`.

It is assumed that the polygon is to be closed by joining the last point to the first point.

The coordinates can contain missing values. The behaviour is similar to that of `lines`, except that instead of breaking a line into several lines, NA values break the polygon into several complete polygons (including closing the last point to the first point). See the examples below.
When multiple polygons are produced, the values of density, angle, col, border, and lty are recycled in the usual manner.

Shading of polygons is only implemented for linear plots: if either axis is on log scale then shading is omitted, with a warning.

Bugs

Self-intersecting polygons may be filled using either the “odd-even” or “non-zero” rule. These fill a region if the polygon border encircles it an odd or non-zero number of times, respectively. Shading lines are handled internally by R according to the fillOddEven argument, but device-based solid fills depend on the graphics device. The windows, pdf and postscript devices have their own fillOddEven argument to control this.

Author(s)

The code implementing polygon shading was donated by Kevin Buhr <buhr@stat.wisc.edu>.

  density = c(10, 20), angle = c(-45, 45))

polypath  
Path Drawing

Description
path draws a path whose vertices are given in x and y.

Usage
polypath(x, y = NULL,
  border = NULL, col = NA, lty = par("lty"),
  rule = "winding", ...)

Arguments
x, y vectors containing the coordinates of the vertices of the path.
col the color for filling the path. The default, NA, is to leave paths unfilled, unless density is specified. (For back-compatibility, NULL is equivalent to NA.) If density is specified with a positive value this gives the color of the shading lines.
border the color to draw the border. The default, NULL, means to use par("fg"). Use border = NA to omit borders. For compatibility with S, border can also be logical, in which case FALSE is equivalent to NA (borders omitted) and TRUE is equivalent to NULL (use the foreground colour).
lty the line type to be used, as in par.
rule character value specifying the path fill mode: either "winding" or "evenodd".
... graphical parameters such as xpd, lend, ljoin and lmitre can be given as arguments.

Details
The coordinates can be passed in a plotting structure (a list with x and y components), a two-column matrix, .... See xy.coords.

It is assumed that the path is to be closed by joining the last point to the first point. The coordinates can contain missing values. The behaviour is similar to that of polygon, except that instead of breaking a polygon into several polygons, NA values break the path into several sub-paths (including closing the last point to the first point in each sub-path). See the examples below.
The distinction between a path and a polygon is that the former can contain holes, as interpreted by the fill rule; these fill a region if the path border encircles it an odd or non-zero number of times, respectively.

Hatched shading (as implemented for polygon()) is not (currently) supported.

Not all graphics devices support this function: for example xfig and pictex do not.

plotRules(c(.1, .1, .6, .6, NA, .4, .9, .9, .4),
    c(.1, .6, .6, .1, NA, .4, .4, .9, .9),
"Overlapping rectangles, one clockwise, other anti-clockwise")

par(op)
```
rasterImage

Draw One or More Raster Images

Description

rasterImage draws a raster image at the given locations and sizes.

Usage

rasterImage(image,
            xleft, ybottom, xright, ytop,
            angle = 0, interpolate = TRUE, ...)

Arguments

- **image** a raster object, or an object that can be coerced to one by `as.raster`.
- **xleft** a vector (or scalar) of left x positions.
- **ybottom** a vector (or scalar) of bottom y positions.
- **xright** a vector (or scalar) of right x positions.
- **ytop** a vector (or scalar) of top y positions.
- **angle** angle of rotation (in degrees, anti-clockwise from positive x-axis, about the bottom-left corner).
- **interpolate** a logical vector (or scalar) indicating whether to apply linear interpolation to the image when drawing.
- **...** graphical parameters.

Details

The positions supplied, i.e., `xleft`, ..., are relative to the current plotting region. If the x-axis goes from 100 to 200 then `xleft` should be larger than 100 and `xright` should be less than 200. The position vectors will be recycled to the length of the longest.

Plotting raster images is not supported on all devices and may have limitations where supported, for example (e.g., for postscript and X11(type = "Xlib") is restricted to opaque colors). Problems with the rendering of raster images have been reported by users of `windows()` devices under Remote Desktop, at least under its default settings.

You should not expect a raster image to be re-sized when an on-screen device is re-sized: whether it is is device-dependent.

See Also

`rect`, `polygon`, and `segments` and others for flexible ways to draw shapes.

`dev.capabilities` to see if it is supported.
Examples

```r
require(grDevices)
## set up the plot region:
op <- par(bg = "thistle")
plot(c(100, 250), c(300, 450), type = "n", xlab = "", ylab = "")
image <- as.raster(matrix(0:1, ncol = 5, nrow = 3))
rasterImage(image, 100, 300, 150, 350, interpolate = FALSE)
rasterImage(image, 100, 400, 150, 450)
rasterImage(image, 200, 300, 250, 450, angle = 15, interpolate = FALSE)
par(op)
```

Description

rect draws a rectangle (or sequence of rectangles) with the given coordinates, fill and border colors.

Usage

```r
rect(xleft, ybottom, xright, ytop, density = NULL, angle = 45,
col = NA, border = NULL, lty = par("lty"), lwd = par("lwd"),
...)```

Arguments

- `xleft` a vector (or scalar) of left x positions.
- `ybottom` a vector (or scalar) of bottom y positions.
- `xright` a vector (or scalar) of right x positions.
- `ytop` a vector (or scalar) of top y positions.
- `density` the density of shading lines, in lines per inch. The default value of NULL means that no shading lines are drawn. A zero value of density means no shading lines whereas negative values (and NA) suppress shading (and so allow color filling).
- `angle` angle (in degrees) of the shading lines.
- `col` color(s) to fill or shade the rectangle(s) with. The default NA (or also NULL) means do not fill, i.e., draw transparent rectangles, unless density is specified.
- `border` color for rectangle border(s). The default means par("fg"). Use border = NA to omit borders. If there are shading lines, border = TRUE means use the same colour for the border as for the shading lines.
- `lty` line type for borders and shading; defaults to "solid".
- `lwd` line width for borders and shading. Note that the use of lwd = 0 (as in the examples) is device-dependent.
- `...` graphical parameters such as xpd, lend, ljoin and lmitre can be given as arguments.
rug

Add a Rug to a Plot

Description

Adds a rug representation (1-d plot) of the data to the plot.

Details

The positions supplied, i.e., xleft, ..., are relative to the current plotting region. If the x-axis goes from 100 to 200 then xleft must be larger than 100 and xright must be less than 200. The position vectors will be recycled to the length of the longest.

It is a graphics primitive used in hist, barplot, legend, etc.

See Also

box for the standard box around the plot; polygon and segments for flexible line drawing.

par for how to specify colors.

Examples

require(grDevices)
## set up the plot region:
op <- par(bg = "thistle")
plot(c(100, 250), c(300, 450), type = "n", xlab = "", ylab = "",
     main = "2 x 11 rectangles; \{ rect(100+i,300+i, 150+i,380+i) \}
     
i <- 4*0:10
## draw rectangles with bottom left (100, 300)+i
## and top right (150, 380)+i
rect(100+i, 300+i, 150+i, 380+i, col = rainbow(11, start = 0.7, end = 0.1))
rect(240-i, 320+i, 250-i, 410+i, col = heat.colors(11), lwd = i/5)
## Background alternating ( transparent / "bg" ) :
j <- 10*0:1:
rect(125+j, 360+j, 141+j, 405+j/2, col = c(NA,0),
     border = "gold", lwd = 2)
rect(125+j, 296+j/2, 141+j, 331+j/5, col = c(NA,"midnightblue"))
mtext("+ 2 x 6 rect(*, col = c(NA,0)) and col = c(NA,\"m..blue\")")
## an example showing colouring and shading
plot(c(100, 200), c(300, 450), type = "n", xlab = "", ylab = "")
rect(100, 300, 125, 350) # transparent
rect(100, 400, 125, 450, col = "green", border = "blue") # coloured
rect(115, 375, 150, 425, col = par("bg"), border = "transparent")
rect(150, 300, 175, 350, density = 10, border = "red")
rect(150, 400, 175, 450, density = 30, col = "blue",
     angle = -30, border = "transparent")
legend(180, 450, legend = 1:4, fill = c(NA, "green", par("fg"), "blue"),
      density = c(NA, NA, 10, 30), angle = c(NA, NA, 10, -30))
par(op)
Usage

rug(x, ticksize = 0.03, side = 1, lwd = 0.5, col = par("fg"),
    quiet = getOption("warn") < 0, ...)

Arguments

  x  A numeric vector

  ticksize  The length of the ticks making up the ‘rug’. Positive lengths give inwards ticks.

  side  On which side of the plot box the rug will be plotted. Normally 1 (bottom) or 3 (top).

  lwd  The line width of the ticks. Some devices will round the default width up to 1.

  col  The colour the ticks are plotted in.

  quiet  logical indicating if there should be a warning about clipped values.

  ...  further arguments, passed to axis, such as line or pos for specifying the location of the rug.

Details

Because of the way rug is implemented, only values of x that fall within the plot region are included. There will be a warning if any finite values are omitted, but non-finite values are omitted silently.

jitter which you may want for ties in x.

Examples

require(stats)  # both 'density' and its default method
with(faithful, {
    plot(density(eruptions, bw = 0.15))
    rug(eruptions)
    rug(jitter(eruptions, amount = 0.01), side = 3, col = "light blue")
})

Description

split.screen defines a number of regions within the current device which can, to some extent, be treated as separate graphics devices. It is useful for generating multiple plots on a single device. Screens can themselves be split, allowing for quite complex arrangements of plots.

screen is used to select which screen to draw in.

erase.screen is used to clear a single screen, which it does by filling with the background colour.

close.screen removes the specified screen definition(s).
Usage

split.screen(figs, screen, erase = TRUE)
screen(n = , new = TRUE)
erase.screen(n = )
close.screen(n, all.screens = FALSE)

Arguments

figs a two-element vector describing the number of rows and the number of columns in a screen matrix or a matrix with 4 columns. If a matrix, then each row describes a screen with values for the left, right, bottom, and top of the screen (in that order) in NDC units, that is 0 at the lower left corner of the device surface, and 1 at the upper right corner.

screen a number giving the screen to be split. It defaults to the current screen if there is one, otherwise the whole device region.

erase logical: should the selected screen be cleared?

n a number indicating which screen to prepare for drawing (screen), erase (erase.screen), or close (close.screen). (close.screen will accept a vector of screen numbers.)

new logical value indicating whether the screen should be erased as part of the preparation for drawing in the screen.

all.screens logical value indicating whether all of the screens should be closed.

Details

The first call to split.screen places \( \mathbb{R} \) into split-screen mode. The other split-screen functions only work within this mode. While in this mode, certain other commands should be avoided (see the Warnings section below). Split-screen mode is exited by the command close.screen(all = TRUE).

If the current screen is closed, close.screen sets the current screen to be the next larger screen number if there is one, otherwise to the first available screen.

Value

split.screen(*) returns a vector of screen numbers for the newly-created screens. With no arguments, split.screen() returns a vector of valid screen numbers.

screen(n) invisibly returns \( n \), the number of the selected screen. With no arguments, screen() returns the number of the current screen.

close.screen() returns a vector of valid screen numbers.

screen, erase.screen, and close.screen all return FALSE if \( \mathbb{R} \) is not in split-screen mode.

Warnings

The recommended way to use these functions is to completely draw a plot and all additions (i.e., points and lines) to the base plot, prior to selecting and plotting on another screen. The behavior associated with returning to a screen to add to an existing plot is unpredictable and may result in problems that are not readily visible.

These functions are totally incompatible with the other mechanisms for arranging plots on a device: par(mfrow), par(mfcol) and layout().
The functions are also incompatible with some plotting functions, such as coplot, which make use of these other mechanisms.

erase.screen will appear not to work if the background colour is transparent (as it is by default on most devices).

par, layout, Devices, dev.*

Examples

if (interactive()) {
  par(bg = "white") # default is likely to be transparent
  split.screen(c(2, 1)) # split display into two screens
  split.screen(c(1, 3), screen = 2) # now split the bottom half into 3
  screen(1) # prepare screen 1 for output
  plot(10:1)
  screen(4) # prepare screen 4 for output
  plot(10:1)
  close.screen(all = TRUE) # exit split-screen mode
  split.screen(c(2, 1)) # split display into two screens
  split.screen(c(1, 2), 2) # split bottom half in two
  plot(1:10) # screen 3 is active, draw plot
  erase.screen() # forgot label, erase and redraw
  plot(1:10, ylab = "ylab 3")
  screen(1) # prepare screen 1 for output
  plot(1:10)
  screen(4) # prepare screen 4 for output
  plot(1:10, ylab = "ylab 4")
  screen(1, FALSE) # return to screen 1, but do not clear
  plot(10:1, axes = FALSE, lty = 2, ylab = "") # overlay second plot
  axis(4) # add tic marks to right-hand axis
  title("Plot 1")
  close.screen(all = TRUE) # exit split-screen mode
}

segments

Add Line Segments to a Plot

Description

Draw line segments between pairs of points.

Usage

segments(x0, y0, x1 = x0, y1 = y0,
       col = par("fg"), lty = par("lty"), lwd = par("lwd"),
       ...)
Arguments

- `x0, y0` coordinates of points from which to draw.
- `x1, y1` coordinates of points to which to draw. At least one must be supplied.
- `col, lty, lwd` graphical parameters as in `par`, possibly vectors. NA values in `col` cause the segment to be omitted.
- `...` further graphical parameters (from `par`), such as `xpd` and the line characteristics `lend`, `ljoin` and `lmitre`.

Details

For each `i`, a line segment is drawn between the point `(x0[i], y0[i])` and the point `(x1[i], y1[i])`. The coordinate vectors will be recycled to the length of the longest.

The graphical parameters `col`, `lty` and `lwd` can be vectors of length greater than one and will be recycled if necessary.

References

See Also

- `arrows`, `polygon` for slightly easier and less flexible line drawing, and `lines` for the usual polygons.

Examples

```r
x <- stats::runif(12); y <- stats::rnorm(12)
i <- order(x, y); x <- x[i]; y <- y[i]
plot(x, y, main = "arrows(.) and segments(.)")
## draw arrows from point to point :
s <- seq(length(x)-1) # one shorter than data
arrows(x[s], y[s], x[s+1], y[s+1], col=1:3)
s <- s[-length(s)]
segments(x[s], y[s], x[s+2], y[s+2], col="pink")
```

smoothScatter

Scatterplots with Smoothed Densities Color Representation

**Description**

`smoothScatter` produces a smoothed color density representation of a scatterplot, obtained through a (2D) kernel density estimate.

**Usage**

```r
smoothScatter(x, y = NULL, nbin = 128, bandwidth,
              colramp = colorRampPalette(c("white", "blues9")),
              nrpoints = 100, ret.selection = FALSE,
              pch = ".", cex = 1, col = "black",
              transformation = function(x) x^.25,
              postPlotHook = box,
              xlab = NULL, ylab = NULL, xlim, ylim,
              xaxs = par("xaxs"), yaxs = par("yaxs"), ...)```
Arguments

- **x, y**
  - the x and y arguments provide the x and y coordinates for the plot. Any reasonable way of defining the coordinates is acceptable. See the function `xy.coords` for details. If supplied separately, they must be of the same length.

- **nbin**
  - numeric vector of length one (for both directions) or two (for x and y separately) specifying the number of equally spaced grid points for the density estimation; directly used as gridsize in `bkde2D()`.

- **bandwidth**
  - numeric vector (length 1 or 2) of smoothing bandwidth(s). If missing, a more or less useful default is used. `bandwidth` is subsequently passed to function `bkde2D`.

- **colramp**
  - function accepting an integer n as an argument and returning n colors.

- **nrpoints**
  - number of points to be superimposed on the density image. The first `nrpoints` points from those areas of lowest regional densities will be plotted. Adding points to the plot allows for the identification of outliers. If all points are to be plotted, choose `nrpoints = Inf`.

- **ret.selection**
  - logical indicating to return the ordered indices of “low density” points if `nrpoints > 0`.

- **pch, cex, col**
  - arguments passed to `points` when `nrpoints > 0`: point symbol, character expansion factor and color, see also `par`.

- **transformation**
  - function mapping the density scale to the color scale.

- **postPlotHook**
  - either `NULL` or a function which will be called (with no arguments) after `image`.

- **xlab, ylab**
  - character strings to be used as axis labels, passed to `image`.

- **xlim, ylim**
  - numeric vectors of length 2 specifying axis limits.

- **xaxs, yaxs, ...**
  - further arguments passed to `image`, e.g., `add=TRUE` or `useRaster=TRUE`.

Details

`smoothScatter` produces a smoothed version of a scatter plot. Two dimensional (kernel density) smoothing is performed by `bkde2D` from package `KernSmooth`. See the examples for how to use this function together with `pairs`.

Value

If `ret.selection` is true, a vector of integers of length `nrpoints` (or smaller, if there are less finite points inside `xlim` and `ylim`) with the indices of the low-density points drawn, ordered with lowest density first.

Author(s)

Florian Hahne at FHCRC, originally

See Also

- `bkde2D` from package `KernSmooth`; `densCols` which uses the same smoothing computations and `blues9` in package `grDevices`.

- `scatter.smooth` adds a `loess` regression smoother to a scatter plot.
Examples

## A largish data set
n <- 10000
x1 <- matrix(rnorm(n), ncol = 2)
x2 <- matrix(rnorm(n, mean = 3, sd = 1.5), ncol = 2)
x <- rbind(x1, x2)

oldpar <- par(mfrow = c(2, 2), mar = c(3, 3, 1, 1), mgp = c(1.5, 0.5, 0))
smoothScatter(x, nrpoints = 0)
smoothScatter(x)

## a different color scheme:
Lab.palette <- colorRampPalette(c("blue", "orange", "red"), space = "Lab")
i.s <- smoothScatter(x, colramp = Lab.palette,
                   ## pch=NA: do not draw them
                   nrpoints = 250, ret.selection = TRUE)
## label the 20 very lowest-density points, the "outliers" (with obs.number):
i.20 <- i.s[1:20]
text(x[i.20,], labels = i.20, cex = 0.75)

## somewhat similar, using identical smoothing computations,
## but considerably less efficient for really large data:
plot(x, col = densCols(x), pch = 20)

## use with pairs:
par(mfrow = c(1, 1))
y <- matrix(rnorm(40000), ncol = 4) + 3*rnorm(10000)
y[, c(2,4)] <- -y[, c(2,4)]
pairs(y, panel = function(...) smoothScatter(..., nrpoints = 0, add = TRUE),
      gap = 0.2)
par(oldpar)

---

spineplot  Spine Plots and Spinograms

Description

Spine plots are a special cases of mosaic plots, and can be seen as a generalization of stacked (or highlighted) bar plots. Analogously, spinograms are an extension of histograms.

Usage

spineplot(x, ...)

## Default S3 method:
spineplot(x, y = NULL,
          breaks = NULL, tol.ylab = 0.05, off = NULL,
          ylevels = NULL, col = NULL,
          main = "", xlab = NULL, ylab = NULL,
          xaxlabels = NULL, yaxlabels = NULL,
          xlim = NULL, ylim = c(0, 1), axes = TRUE, ...)
### S3 method for class 'formula'

```r
spineplot(formula, data = NULL, 
  breaks = NULL, tol.ylab = 0.05, off = NULL, 
  ylevels = NULL, col = NULL, 
  main = "", xlab = NULL, ylab = NULL, 
  xaxlabels = NULL, yaxlabels = NULL, 
  xlim = NULL, ylim = c(0, 1), axes = TRUE, ..., 
  subset = NULL, drop.unused.levels = FALSE)
```

**Arguments**

- `x` an object, the default method expects either a single variable (interpreted to be the explanatory variable) or a 2-way table. See details.
- `y` a "factor" interpreted to be the dependent variable
- `formula` a "formula" of type \( y \sim x \) with a single dependent "factor" and a single explanatory variable.
- `data` an optional data frame.
- `breaks` if the explanatory variable is numeric, this controls how it is discretized. `breaks` is passed to `hist` and can be a list of arguments.
- `tol.ylab` convenience tolerance parameter for y-axis annotation. If the distance between two labels drops under this threshold, they are plotted equidistantly.
- `off` vertical offset between the bars (in per cent). It is fixed to 0 for spinograms and defaults to 2 for spine plots.
- `ylevels` a character or numeric vector specifying in which order the levels of the dependent variable should be plotted.
- `col` a vector of fill colors of the same length as `levels(y)`. The default is to call `gray.colors`.
- `main`, `xlab`, `ylab` character strings for annotation
- `xaxlabels`, `yaxlabels` character vectors for annotation of x and y axis. Default to `levels(y)` and `levels(x)`, respectively for the spine plot. For `xaxlabels` in the spinogram, the breaks are used.
- `xlim`, `ylim` the range of x and y values with sensible defaults.
- `axes` logical. If `FALSE` all axes (including those giving level names) are suppressed.
- `...` additional arguments passed to `rect`.
- `subset` an optional vector specifying a subset of observations to be used for plotting.
- `drop.unused.levels` should factors have unused levels dropped? Defaults to `FALSE`.

**Details**

`spineplot` creates either a spinogram or a spine plot. It can be called via `spineplot(x, y)` or `spineplot(y ~ x)` where `y` is interpreted to be the dependent variable (and has to be categorical) and `x` the explanatory variable. `x` can be either categorical (then a spine plot is created) or numerical (then a spinogram is plotted). Additionally, `spineplot` can also be called with only a single argument which then has to be a 2-way table, interpreted to correspond to `table(x, y)`.

Both, spine plots and spinograms, are essentially mosaic plots with special formatting of spacing and shading. Conceptually, they plot \( P(y|x) \) against \( P(x) \). For the spine plot (where both \( x \) and \( y \)
are categorical), both quantities are approximated by the corresponding empirical relative frequen-
cies. For the spino gram (where \( x \) is numerical), \( x \) is first discretized (by calling \texttt{hist} with \texttt{breaks} argument) and then empirical relative frequencies are taken.

Thus, spine plots can also be seen as a generalization of stacked bar plots where not the heights but the widths of the bars corresponds to the relative frequencies of \( x \). The heights of the bars then correspond to the conditional relative frequencies of \( y \) in every \( x \) group. Analogously, spinograms extend stacked histograms.

Value
The table visualized is returned invisibly.

Examples

```r
## treatment and improvement of patients with rheumatoid arthritis
treatment <- factor(rep(c(1, 2), c(43, 41)), levels = c(1, 2),
                   labels = c("placebo", "treated"))
improved <- factor(rep(c(1, 2, 3, 1, 2, 3), c(29, 7, 7, 13, 7, 21)),
                   levels = c(1, 2, 3),
                   labels = c("none", "some", "marked"))

## (dependence on a categorical variable)
(spineplot(improved ~ treatment))

## applications and admissions by department at UC Berkeley
## (two-way tables)
(spineplot(marginSums(UCBAdmissions, c(3, 2)),
           main = "Applications at UCB"))
(spineplot(marginSums(UCBAdmissions, c(3, 1)),
           main = "Admissions at UCB"))

## NASA space shuttle o-ring failures
fail <- factor(c(2, 2, 2, 2, 1, 1, 1, 1, 1, 2, 1, 2, 1, 2, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1),
               levels = c(1, 2), labels = c("no", "yes"))
```
**stars**

*Star (Spider/Radar) Plots and Segment Diagrams*

**Description**

Draw star plots or segment diagrams of a multivariate data set. With one single location, also draws 'spider' (or 'radar') plots.

**Usage**

```r
glons <- c(53, 57, 58, 63, 66, 67, 67, 68, 69, 70, 70, 70, 72, 73, 75, 75, 76, 76, 78, 79, 81)

## (dependence on a numerical variable)
(spineplot(fail ~ temperature))
(spineplot(fail ~ temperature, breaks = 3))
(spineplot(fail ~ temperature, breaks = quantile(temperature)))

## highlighting for failures
spineplot(fail ~ temperature, ylevels = 2:1)
```

**Arguments**

- `x`: matrix or data frame of data. One star or segment plot will be produced for each row of `x`. Missing values (NA) are allowed, but they are treated as if they were 0 (after scaling, if relevant).
- `full`: logical flag: if `TRUE`, the segment plots will occupy a full circle. Otherwise, they occupy the (upper) semicircle only.
- `scale`: logical flag: if `TRUE`, the columns of the data matrix are scaled independently so that the maximum value in each column is 1 and the minimum is 0. If `FALSE`, the presumption is that the data have been scaled by some other algorithm to the range $[0,1]$.
- `radius`: logical flag: in `TRUE`, the radii corresponding to each variable in the data will be drawn.
stars

labels vector of character strings for labeling the plots. Unlike the S function stars, no attempt is made to construct labels if labels = NULL.

locations Either two column matrix with the x and y coordinates used to place each of the segment plots; or numeric of length 2 when all plots should be superimposed (for a 'spider plot'). By default, locations = NULL, the segment plots will be placed in a rectangular grid.

nrow, ncol integers giving the number of rows and columns to use when locations is NULL. By default, nrow == ncol, a square layout will be used.

len scale factor for the length of radii or segments.

key.loc vector with x and y coordinates of the unit key.

key.labels vector of character strings for labeling the segments of the unit key. If omitted, the second component of dimnames(x) is used, if available.

key.xpd clipping switch for the unit key (drawing and labeling), see par("xpd").

xlim vector with the range of x coordinates to plot.

ylim vector with the range of y coordinates to plot.

flip.labels logical indicating if the label locations should flip up and down from diagram to diagram. Defaults to a somewhat smart heuristic.

draw.segments logical. If TRUE draw a segment diagram.

col.segments color vector (integer or character, see par), each specifying a color for one of the segments (variables). Ignored if draw.segments = FALSE.

col.stars color vector (integer or character, see par), each specifying a color for one of the stars (cases). Ignored if draw.segments = TRUE.

col.lines color vector (integer or character, see par), each specifying a color for one of the lines (cases). Ignored if draw.segments = TRUE.

axes logical flag: if TRUE axes are added to the plot.

frame.plot logical flag: if TRUE, the plot region is framed.

main a main title for the plot.

sub a sub title for the plot.

xlab a label for the x axis.

ylab a label for the y axis.

cex character expansion factor for the labels.

lwd line width used for drawing.

lty line type used for drawing.

xpd logical or NA indicating if clipping should be done, see par(xpd = .).

mar argument to par(mar = *), typically choosing smaller margins than by default.

... further arguments, passed to the first call of plot(), see plot.default and to box() if frame.plot is true.

add logical, if TRUE add stars to current plot.

plot logical, if FALSE, nothing is plotted.

Details

Missing values are treated as 0.

Each star plot or segment diagram represents one row of the input x. Variables (columns) start on the right and wind counterclockwise around the circle. The size of the (scaled) column is shown by the distance from the center to the point on the star or the radius of the segment representing the variable.

Only one page of output is produced.
stars

Value

Returns the locations of the plots in a two column matrix, invisibly when plot = TRUE.

Note

This code started life as spatial star plots by David A. Andrews. Prior to R 1.4.1, scaling only shifted the maximum to 1, although documented as here.

stars(USJudge, labels = Snam, scale = FALSE,
key.loc = c(13, 1.5), radius = FALSE)
loc <- stars(USJudge, labels = NULL, scale = FALSE,
radius = FALSE, frame.plot = TRUE,
key.loc = c(13, 1.5), main = "Judge not ...", len = 1.2)
text(loc, Snam, col = "blue", cex = 0.8, xpd = TRUE)
## Stem

Stem-and-Leaf Plots

### Description

stem produces a stem-and-leaf plot of the values in x. The parameter scale can be used to expand the scale of the plot. A value of scale = 2 will cause the plot to be roughly twice as long as the default.

### Usage

```r
stem(x, scale = 1, width = 80, atom = 1e-08)
```

### Arguments

- `x` a numeric vector.
- `scale` This controls the plot length.
- `width` The desired width of plot.
- `atom` a tolerance.

### Details

Infinite and missing values in x are discarded.

### References

### Examples

```r
stem(islands)
stem(log10(islands))
```
Description

stripchart produces one dimensional scatter plots (or dot plots) of the given data. These plots are a good alternative to boxplots when sample sizes are small.

Usage

stripchart(x, ...)

## S3 method for class 'formula'
stripchart(x, data = NULL, dlab = NULL, ..., 
subset, na.action = NULL)

## Default S3 method:
stripchart(x, method = "overplot", jitter = 0.1, offset = 1/3, 
vertical = FALSE, group.names, add = FALSE, 
at = NULL, xlim = NULL, ylim = NULL, 
ylab = NULL, xlab = NULL, dlab = "", glab = "", 
log = ",", pch = 0, col = par("fg"), cex = par("cex"), 
axes = TRUE, frame.plot = axes, ...)

Arguments

x

the data from which the plots are to be produced. In the default method the data can be specified as a single numeric vector, or as list of numeric vectors, each corresponding to a component plot. In the formula method, a symbolic specification of the form \( y \sim g \) can be given, indicating the observations in the vector \( y \) are to be grouped according to the levels of the factor \( g \). NAs are allowed in the data.

data

a data.frame (or list) from which the variables in \( x \) should be taken.

subset

an optional vector specifying a subset of observations to be used for plotting.

na.action

a function which indicates what should happen when the data contain NAs. The default is to ignore missing values in either the response or the group.

... additional parameters passed to the default method, or by it to plot.window, points, axis and title to control the appearance of the plot.

method

the method to be used to separate coincident points. The default method "overplot" causes such points to be overplotted, but it is also possible to specify "jitter" to jitter the points, or "stack" have coincident points stacked. The last method only makes sense for very granular data.

jitter

when method = "jitter" is used, jitter gives the amount of jittering applied.

offset

when stacking is used, points are stacked this many line-heights (symbol widths) apart.

vertical

when vertical is TRUE the plots are drawn vertically rather than the default horizontal.
group.names  group labels which will be printed alongside (or underneath) each plot.
add logical, if true add the chart to the current plot.
at numeric vector giving the locations where the charts should be drawn, particularly when add = TRUE; defaults to 1:n where n is the number of boxes.
ylab, xlab labels: see title.
dlab, glab alternate way to specify axis labels: see ‘Details’.
xlim, ylim plot limits: see plot.window.
log on which axes to use a log scale: see plot.default
pch, col, cex Graphical parameters: see par.
axes, frame.plot Axis control: see plot.default.

Details

Extensive examples of the use of this kind of plot can be found in Box, Hunter and Hunter or Seber and Wild.

The dlab and glab labels may be used instead of xlab and ylab if those are not specified. dlab applies to the continuous data axis (the X axis unless vertical is TRUE), glab to the group axis.

Examples

x <- stats::rnorm(50)
xr <- round(x, 1)
stripchart(x) ; m <- mean(par("usr")[1:2])
text(m, 1.04, "stripchart(x, \"overplot\")")
stripchart(xr, method = "stack", add = TRUE, at = 1.2)
text(m, 1.35, "stripchart(round(x,1), \"stack\")")
stripchart(xr, method = "jitter", add = TRUE, at = 0.7)
text(m, 0.85, "stripchart(round(x,1), \"jitter\")")

stripchart(decrease ~ treatment,
    main = "stripchart(OrchardSprays)",
    vertical = TRUE, log = "y", data = OrchardSprays)

stripchart(decrease ~ treatment, at = c(1:8)*2,
    main = "stripchart(OrchardSprays)",
    vertical = TRUE, log = "y", data = OrchardSprays)

strwidth

Plotting Dimensions of Character Strings and Math Expressions

Description

These functions compute the width or height, respectively, of the given strings or mathematical expressions s[i] on the current plotting device in user coordinates, inches or as fraction of the figure width par("fin").

Usage

strwidth(s, units = "user", cex = NULL, font = NULL, vfont = NULL, …)
strheight(s, units = "user", cex = NULL, font = NULL, vfont = NULL, …)
Arguments

s  a character or expression vector whose dimensions are to be determined. Other objects are coerced by as.graphicsAnnot.

units  character indicating in which units s is measured; should be one of "user", "inches", "figure"; partial matching is performed.

cex  numeric character expansion factor; multiplied by par("cex") yields the final character size; the default NULL is equivalent to 1.

font, vfont, ...  additional information about the font, possibly including the graphics parameter "family": see text.

Details

Note that the ‘height’ of a string is determined only by the number of linefeeds ("\n") it contains: it is the (number of linefeeds - 1) times the line spacing plus the height of "M" in the selected font. For an expression it is the height of the bounding box as computed by plotmath. Thus in both cases it is an estimate of how far above the final baseline the typeset object extends. (It may also extend below the baseline.) The inter-line spacing is controlled by cex, par("lheight") and the ‘point size’ (but not the actual font in use).

Measurements in "user" units (the default) are only available after plot.new has been called – otherwise an error is thrown.

Value

Numeric vector with the same length as s, giving the estimate of width or height for each s[i]. NA strings are given width and height 0 (as they are not plotted).

Examples

str.ex <- c("W","w","I",".","WwI.")
op <- par(pty = "s"); plot(1:100, 1:100, type = "n")
sw <- strwidth(str.ex); sw
all.equal(sum(sw[1:4]), sw[5])
#- since the last string contains the others
sw.i <- strwidth(str.ex, "inches"); 25.4 * sw.i  # width in [mm]
unique(sw / sw.i)
# constant factor: 1 value
mean(sw.i / strwidth(str.ex, "fig")) / par('fin')[1]  # = 1: are the same

## See how letters fall in classes
## -- depending on graphics device and font!
all.lett <- c(letters, LETTERS)
shL <- strheight(all.lett, units = "inches") * 72  # 'big points'
table(shL)  # all have same heights ...
mean(shL)/par("cin")[2]  # around 0.6

(swL <- strwidth(all.lett, units = "inches") * 72)  # 'big points'
split(all.lett, factor(round(swL, 2)))
sunflowerplot

## Produce a Sunflower Scatter Plot

### Description

Multiple points are plotted as 'sunflowers' with multiple leaves ('petals') such that overplotting is visualized instead of accidental and invisible.

### Usage

sunflowerplot(x, ...)

```r
## Default S3 method:
sunflowerplot(x, y = NULL, number, log = "", digits = 6,
xlab = NULL, ylab = NULL, xlim = NULL, ylim = NULL,
add = FALSE, rotate = FALSE,
pch = 16, cex = 0.8, cex.fact = 1.5,
col = par("col"), bg = NA, size = 1/8, seg.col = 2,
seg.lwd = 1.5, ...)
```

```r
## S3 method for class 'formula'
sunflowerplot(formula, data = NULL, xlab = NULL, ylab = NULL, ...
subset, na.action = NULL)
```

### Arguments

- **x**: numeric vector of x-coordinates of length n, say, or another valid plotting structure, as for `plot.default`, see also `xy.coords`.
- **y**: numeric vector of y-coordinates of length n.
- **number**: integer vector of length n. number[i] = number of replicates for (x[i],y[i]), may be 0. Default (missing(number)): compute the exact multiplicity of the points x[i],y[i], via `xyTable()`.
- **log**: character indicating log coordinate scale, see `plot.default`.
- **digits**: when number is computed (i.e., not specified), x and y are rounded to digits significant digits before multiplicities are computed.
- **xlab, ylab**: character label for x-, or y-axis, respectively.
- **xlim, ylim**: numeric(2) limiting the extents of the x-, or y-axis.
- **add**: logical; should the plot be added on a previous one? Default is FALSE.
- **rotate**: logical; if TRUE, randomly rotate the sunflowers (preventing artefacts).
- **pch**: plotting character to be used for points (number[i]==1) and center of sunflowers.
sunflowerplot

cex numeric; character size expansion of center points (s. pch).
cex.fact numeric shrinking factor to be used for the center points when there are flower leaves, i.e., cex / cex.fact is used for these.
col, bg colors for the plot symbols, passed to plot.default.
size of sunflower leaves in inches, 1[in] := 2.54[cm]. Default: 1/8", approximately 3.2mm.
seg.col color to be used for the segments which make the sunflowers leaves, see par(col=); col = "gold" reminds of real sunflowers.
seg.lwd numeric; the line width for the leaves’ segments.
... further arguments to plot [if add = FALSE], or to be passed to or from another method.
formula a formula, such as y ~ x.
data a data.frame (or list) from which the variables in formula should be taken.
subset an optional vector specifying a subset of observations to be used in the fitting process.
na.action a function which indicates what should happen when the data contain NAs. The default is to ignore case with missing values.

Details

This is a generic function with default and formula methods.

For number[1] == 1, a (slightly enlarged) usual plotting symbol (pch) is drawn. For number[1] > 1, a small plotting symbol is drawn and number[1] equi-angular ‘rays’ emanate from it.

If rotate = TRUE and number[1] >= 2, a random direction is chosen (instead of the y-axis) for the first ray. The goal is to jitter the orientations of the sunflowers in order to prevent artefactual visual impressions.

Value

A list with three components of same length,

x x coordinates
y y coordinates
number number

Use xyTable() (from package grDevices) if you are only interested in this return value.

Side Effects

A scatter plot is drawn with ‘sunflowers’ as symbols.

Examples

```r
require(stats) # for rnorm
require(grDevices)

# 'number' is computed automatically:
sunflowerplot(iris[, 3:4])
# Imitating Chambers et al, p.109, closely:
sunflowerplot(iris[, 3:4], cex = .2, cex.fact = 1, size = .035, seg.lwd = .8)
# or
sunflowerplot(Petal.Width ~ Petal.Length, data = iris,
              cex = .2, cex.fact = 1, size = .035, seg.lwd = .8)

sunflowerplot(x = sort(2*round(rnorm(100))), y = round(rnorm(100), 0),
              main = "Sunflower Plot of Rounded N(0,1)"
# Similarly using a "xyTable" argument:
xyT <- xyTable(x = sort(2*round(rnorm(100))), y = round(rnorm(100), 0),
                digits = 3)
utils::str(xyT, vec.len = 20)
sunflowerplot(xyT, main = "2nd Sunflower Plot of Rounded N(0,1)"

# A 'marked point process' (explicit 'number' argument):
sunflowerplot(rnorm(100), rnorm(100), number = rpois(n = 100, lambda = 2),
             main = "Sunflower plot (marked point process)",
             rotate = TRUE, col = "blue4")
```

symbols

*Draw Symbols (Circles, Squares, Stars, Thermometers, Boxplots)*

Description

This function draws symbols on a plot. One of six symbols; *circles*, *squares*, *rectangles*, *stars*, *thermometers*, and *boxplots*, can be plotted at a specified set of x and y coordinates. Specific aspects of the symbols, such as relative size, can be customized by additional parameters.

Usage

```
symbols(x, y = NULL, circles, squares, rectangles, stars, thermometers, boxplots, inches = TRUE, add = FALSE, fg = par("col"), bg = NA, xlab = NULL, ylab = NULL, main = NULL, xlim = NULL, ylim = NULL, ...)```
Arguments

- **x, y**
  the x and y co-ordinates for the centres of the symbols. They can be specified in any way which is accepted by `xy.coords`.

- **circles**
  a vector giving the radii of the circles.

- **squares**
  a vector giving the length of the sides of the squares.

- **rectangles**
  a matrix with two columns. The first column gives widths and the second the heights of rectangles.

- **stars**
  a matrix with three or more columns giving the lengths of the rays from the center of the stars. NA values are replaced by zeroes.

- **thermometers**
  a matrix with three or four columns. The first two columns give the width and height of the thermometer symbols. If there are three columns, the third is taken as a proportion: the thermometers are filled (using colour fg) from their base to this proportion of their height. If there are four columns, the third and fourth columns are taken as proportions and the thermometers are filled between these two proportions of their heights. The part of the box not filled in fg will be filled in the background colour (default transparent) given by bg.

- **boxplots**
  a matrix with five columns. The first two columns give the width and height of the boxes, the next two columns give the lengths of the lower and upper whiskers and the fifth the proportion (with a warning if not in [0,1]) of the way up the box that the median line is drawn.

- **inches**
  TRUE, FALSE or a positive number. See ‘Details’.

- **add**
  if add is TRUE, the symbols are added to an existing plot, otherwise a new plot is created.

- **fg**
  colour(s) the symbols are drawn in.

- **bg**
  if specified, the symbols are filled with colour(s), the vector bg being recycled to the number of symbols. The default is to leave the symbols unfilled.

- **xlab**
  the x label of the plot if add is not true. Defaults to the deparse d expression used for x.

- **ylab**
  the y label of the plot. Unused if add = TRUE.

- **main**
  a main title for the plot. Unused if add = TRUE.

- **xlim**
  numeric vector of length 2 giving the x limits for the plot. Unused if add = TRUE.

- **ylim**
  numeric vector of length 2 giving the y limits for the plot. Unused if add = TRUE.

- **...**
  graphics parameters can also be passed to this function, as can the plot aspect ratio asp (see `plot.window`).

Details

Observations which have missing coordinates or missing size parameters are not plotted. The exception to this is stars. In that case, the length of any ray which is NA is reset to zero.

Argument inches controls the sizes of the symbols. If TRUE (the default), the symbols are scaled so that the largest dimension of any symbol is one inch. If a positive number is given the symbols are scaled to make largest dimension this size in inches (so TRUE and 1 are equivalent). If inches is FALSE, the units are taken to be those of the appropriate axes. (For circles, squares and stars the units of the x axis are used. For boxplots, the lengths of the whiskers are regarded as dimensions alongside width and height when scaling by inches, and are otherwise interpreted in the units of the y axis.)
Circles of radius zero are plotted at radius one pixel (which is device-dependent). Circles of a very small non-zero radius may or may not be visible, and may be smaller than circles of radius zero. On windows devices circles are plotted at radius at least one pixel as some Windows versions omit smaller circles.

`stars` for drawing *stars* with a bit more flexibility.

If you are thinking about doing ‘bubble plots’ by `symbols(*, circles=*).` you should really consider using `sunflowerplot` instead.

Examples

```r
require(stats); require(grDevices)
x <- 1:10
y <- sort(10*runif(10))
z <- runif(10)
z3 <- cbind(z, 2*runif(10), runif(10))
symbols(x, y, thermometers = cbind(.5, 1, z), inches = .5, fg = 1:10)
symbols(x, y, thermometers = z3, inches = FALSE)
text(x, y, apply(format(round(z3, digits = 2)), 1, paste, collapse = ""),
     adj = c(-.2,0), cex = .75, col = "purple", xpd = NA)

## Note that example(trees) shows more sensible plots!
N <- nrow(trees)
with(trees, {
## Girth is diameter in inches
symbols(Height, Volume, circles = Girth/24, inches = FALSE,
       main = "Trees' Girth") # xlab and ylab automatically
## Colours too:
op <- palette(rainbow(N, end = 0.9))
symbols(Height, Volume, circles = Girth/16, inches = FALSE, bg = 1:N,
       fg = "gray30", main = "symbols(*, circles = Girth/16, bg = 1:N")
palette(op)
})
```

**text**

*Add Text to a Plot*

**Description**

text draws the strings given in the vector `labels` at the coordinates given by `x` and `y`. `y` may be missing since `xy.coords(x,y)` is used for construction of the coordinates.
text(x, ...)

## Default S3 method:
text(x, y = NULL, labels = seq_along(x$x), adj = NULL,
pos = NULL, offset = 0.5, vfont = NULL,
cex = 1, col = NULL, font = NULL, ...)

### Arguments

- **x, y**
  numeric vectors of coordinates where the text labels should be written. If the length of x and y differs, the shorter one is recycled.

- **labels**
  a character vector or expression specifying the text to be written. An attempt is made to coerce other language objects (names and calls) to expressions, and vectors and other classed objects to character vectors by `as.character`. If `labels` is longer than `x` and `y`, the coordinates are recycled to the length of `labels`.

- **adj**
  one or two values in `[0, 1]` which specify the x (and optionally y) adjustment (‘justification’) of the labels, with 0 for left/bottom, 1 for right/top, and 0.5 for centered. On most devices values outside `[0, 1]` will also work. See below.

- **pos**
  a position specifier for the text. If specified this overrides any `adj` value given. Values of 1, 2, 3 and 4, respectively indicate positions below, to the left of, above and to the right of the specified `(x,y)` coordinates.

- **offset**
  when `pos` is specified, this value controls the distance (‘offset’) of the text label from the specified coordinate in fractions of a character width.

- **vfont**
  NULL for the current font family, or a character vector of length 2 for Hershey vector fonts. The first element of the vector selects a typeface and the second element selects a style. Ignored if `labels` is an expression.

- **cex**
  numeric character expansion factor; multiplied by `par("cex")` yields the final character size. NULL and NA are equivalent to 1.0.

- **col, font**
  the color and (if `vfont = NULL`) font to be used, possibly vectors. These default to the values of the global graphical parameters in `par()`.

- **...**
  further graphical parameters (from `par`), such as `srt`, `family` and `xpd`.

### Details

- **labels** must be of type character or expression (or be coercible to such a type). In the latter case, quite a bit of mathematical notation is available such as sub- and superscripts, greek letters, fractions, etc.

- **adj** allows adjustment of the text position with respect to `(x,y)`. Values of 0, 0.5, and 1 specify that `(x,y)` should align with the left/bottom, middle and right/top of the text, respectively. The default is for centered text, i.e., `adj = c(0.5,NA)`. Accurate vertical centering needs character metric information on individual characters which is only available on some devices. Vertical alignment is done slightly differently for character strings and for expressions: `adj = c(0,0)` means to left-justify and to align on the baseline for strings but on the bottom of the bounding box for expressions. This also affects vertical centering: for strings the centering excludes any descenders whereas for expressions it includes them. Using NA for strings centers them, including descenders.

The `pos` and `offset` arguments can be used in conjunction with values returned by `identify` to recreate an interactively labelled plot.
Text can be rotated by using graphical parameters srt (see par). When adj is specified, a non-zero srt rotates the label about (x,y). If pos is specified, srt rotates the text about the point on its bounding box which is closest to (x,y): top center for pos = 1, right center for pos = 2, bottom center for pos = 3, and left center for pos = 4. The pos interface is not as useful for rotated text because the result is no longer centered vertically or horizontally with respect to (x,y). At present there is no interface in the graphics package for directly rotating text about its center which is achievable however by fiddling with adj and srt simultaneously.

Graphical parameters col, cex and font can be vectors and will then be applied cyclically to the labels (and extra values will be ignored). NA values of font are replaced by par("font"), and similarly for col.

Labels whose x, y or labels value is NA are omitted from the plot.

What happens when font = 5 (the symbol font) is selected can be both device- and locale-dependent. Most often labels will be interpreted in the Adobe symbol encoding, so e.g. "d" is delta, and "\300" is aleph.

Euro symbol

The Euro symbol may not be available in older fonts. In current versions of Adobe symbol fonts it is character 160, so text(x,y,"\xA0",font = 5) may work. People using Western European locales on Unix-alikes can probably select ISO-8895-15 (Latin-9) which has the Euro as character 165: this can also be used for postscript and pdf. It is \u20ac in Unicode, which can be used in UTF-8 locales.

The Euro should be rendered correctly by X11 in UTF-8 locales, but the corresponding single-byte encoding in postscript and pdf will need to be selected as ISOLatin9.enc (and the font will need to contain the Euro glyph, which for example older printers may not).

Examples

plot(-1:1, -1:1, type = "n", xlab = "Re", ylab = "Im")
K <- 16; text(exp(1i * 2 * pi * (1:K) / K), col = 2)

## The following two examples use latin1 characters: these may not
## appear correctly (or be omitted entirely).
plot(1:10, 1:10, main = "text(...) examples\n-------------------

sub = "R is GNU ©, but not © ...")
mtext("<Latin-1 accented chars>: éè øØ å<Å æ<Æ", side = 3)
points(c(6,2), c(2,1), pch = 3, cex = 4, col = "red")
text(6, 2, "the text is CENTERED around (x,y) = (6,2) by default",
     adj = c(0,0))
text(2, 1, "or Left/Bottom - JUSTIFIED at (2,1) by 'adj = c(0,0)'",
     adj = c(0,0))
text(4, 9, expression(hat(beta) == (X^t * X)^{-1} * X^t * y))
title

Plot Annotation

Description

This function can be used to add labels to a plot. Its first four principal arguments can also be used as arguments in most high-level plotting functions. They must be of type character or expression. In the latter case, quite a bit of mathematical notation is available such as sub- and superscripts, greek letters, fractions, etc: see plotmath

Usage

title(main = NULL, sub = NULL, xlab = NULL, ylab = NULL,
       line = NA, outer = FALSE, ...)

Arguments

main The main title (on top) using font, size (character expansion) and color
sub Sub-title (at bottom) using font, size and color
xlab X axis label using font, size and color
ylab Y axis label, same font attributes as xlab.
line specifying a value for line overrides the default placement of labels, and places them this many lines outwards from the plot edge.
outer a logical value. If TRUE, the titles are placed in the outer margins of the plot.
... further graphical parameters from par. Use e.g., col.main or cex.sub instead of just col or cex. adj controls the justification of the titles. xpd can be used to set the clipping region: this defaults to the figure region unless outer = TRUE, otherwise the device region and can only be increased. mgp controls the default placing of the axis titles.

Details

The labels passed to title can be character strings or language objects (names, calls or expressions), or a list containing the string to be plotted, and a selection of the optional modifying graphical parameters cex=, col= and font=. Other objects will be coerced by as.graphicsAnnot.

The position of main defaults to being vertically centered in (outer) margin 3 and justified horizontally according to par ("adj") on the plot region (device region for outer = TRUE).
The positions of `xlab`, `ylab` and `sub` are line (default for `xlab` and `ylab` being `par("mgp")[1]` and increased by 1 for sub) lines (of height `par("mex")`) into the appropriate margin, justified in the text direction according to `par("adj")` on the plot/device region.

### Examples

```r
plot(cars, main = "") # here, could use main directly
title(main = "Stopping Distance versus Speed")

plot(cars, main = "")
title(main = list("Stopping Distance versus Speed", cex = 1.5,
                  col = "red", font = 3))

## Specifying "..." :
plot(1, col.axis = "sky blue", col.lab = "thistle")
title("Main Title", sub = "sub title",
      cex.main = 2, font.main = 4, col.main = "blue",
      cex.sub = 0.75, font.sub = 3, col.sub = "red")

x <- seq(-4, 4, len = 101)
y <- cbind(sin(x), cos(x))
matplot(x, y, type = "l", xaxt = "n",
       main = expression(paste(plain(sin) * phi, " and ",
                            plain(cos) * phi)),
       ylab = expression("sin" * phi, "cos" * phi), # only 1st is taken
       xlab = expression(paste("Phase Angle ", phi)),
       col.main = "blue")
axis(1, at = c(-pi, -pi/2, 0, pi/2, pi),
     labels = expression(-pi, -pi/2, 0, pi/2, pi))
abline(h = 0, v = pi/2 * c(-1,1), lty = 2, lwd = .1, col = "gray70")
```

### Description

`xinch` and `yinch` convert the specified number of inches given as their arguments into the correct units for plotting with graphics functions. Usually, this only makes sense when normal coordinates are used, i.e., *no* log scale (see the `log` argument to `par`).

`xyinch` does the same for a pair of numbers `xy`, simultaneously.
**xspline**

**Usage**

```r
xinch(x = 1, warn.log = TRUE)
yinch(y = 1, warn.log = TRUE)
xyinch(xy = 1, warn.log = TRUE)
```

**Arguments**

- `x`, `y`: numeric vector
- `xy`: numeric of length 1 or 2.
- `warn.log`: logical; if TRUE, a warning is printed in case of active log scale.

**Examples**

```r
all(c(xinch(), yinch()) == xyinch()) # TRUE
xyinch()
xyinch # to see that is really delta("usr") / "pin"
```

```r
## plot labels offset 0.12 inches to the right
## of plotted symbols in a plot
with(mtcars, {
  plot(mpg, disp, pch = 19, main = "Motor Trend Cars")
  text(mpg + xinch(0.12), disp, row.names(mtcars),
       adj = 0, cex = .7, col = "blue")
})
```

---

**xspline**  
*Draw an X-spline*

**Description**

Draw an X-spline, a curve drawn relative to control points.

**Usage**

```r
xspline(x, y = NULL, shape = 0, open = TRUE, repEnds = TRUE,
        draw = TRUE, border = par("fg"), col = NA, ...)
```

**Arguments**

- `x, y`: vectors containing the coordinates of the vertices of the polygon. See `xy.coords` for alternatives.
- `shape`: A numeric vector of values between -1 and 1, which control the shape of the spline relative to the control points.
- `open`: A logical value indicating whether the spline is an open or a closed shape.
- `repEnds`: For open X-splines, a logical value indicating whether the first and last control points should be replicated for drawing the curve. Ignored for closed X-splines.
- `draw`: logical: should the X-spline be drawn? If false, a set of line segments to draw the curve is returned, and nothing is drawn.
- `border`: the color to draw the curve. Use `border = NA` to omit borders.
- `col`: the color for filling the shape. The default, NA, is to leave unfilled.
- `...`: graphical parameters such as `lty`, `xpd`, `lend`, `ljoin` and `lmitre` can be given as arguments.
Details

An X-spline is a line drawn relative to control points. For each control point, the line may pass through (interpolate) the control point or it may only approach (approximate) the control point; the behaviour is determined by a shape parameter for each control point.

If the shape parameter is greater than zero, the spline approximates the control points (and is very similar to a cubic B-spline when the shape is 1). If the shape parameter is less than zero, the spline interpolates the control points (and is very similar to a Catmull-Rom spline when the shape is -1).

If the shape parameter is 0, the spline forms a sharp corner at that control point.

For open X-splines, the start and end control points must have a shape of 0 (and non-zero values are silently converted to zero).

For open X-splines, by default the start and end control points are replicated before the curve is drawn. A curve is drawn between (interpolating or approximating) the second and third of each set of four control points, so this default behaviour ensures that the resulting curve starts at the first control point you have specified and ends at the last control point. The default behaviour can be turned off via the `repEnds` argument.

Value

If `draw = TRUE`, NULL otherwise a list with elements `x` and `y` which could be passed to `lines`, `polygon` and so on. Invisible in both cases.

Note

Two-dimensional splines need to be created in an isotropic coordinate system. Device coordinates are used (with an anisotropy correction if needed.)

Chapter 6

The grid package

grid-package

Description
A rewrite of the graphics layout capabilities, plus some support for interaction.

Details
This package contains a graphics system which supplements S-style graphics (see the graphics package).

Further information is available in the following vignettes:

- grid
  - Introduction to grid (../doc/grid.pdf)
- displaylist
  - Display Lists in grid (../doc/displaylist.pdf)
- frame
  - Frames and packing grobs (../doc/frame.pdf)

Maintainer: R Core Team <R-core@r-project.org>
References

absolute.size

Absolute Size of a Grob

Description

This function converts a unit object into absolute units. Absolute units are unaffected, but non-absolute units are converted into "null" units.

Usage

absolute.size(unit)

Arguments

unit

An object of class "unit".

Details

Absolute units are things like "inches", "cm", and "lines". Non-absolute units are "npc" and "native".

This function is designed to be used in widthDetails and heightDetails methods.

Value

An object of class "unit".

Author(s)

Paul Murrell

See Also

widthDetails and heightDetails methods.
**arrow**

*Describe arrows to add to a line.*

**Description**

Produces a description of what arrows to add to a line. The result can be passed to a function that draws a line, e.g., `grid.lines`.

**Usage**

```r
arrow(angle = 30, length = unit(0.25, "inches"),
     ends = "last", type = "open")
```

**Arguments**

- **angle**
  The angle of the arrow head in degrees (smaller numbers produce narrower, pointier arrows). Essentially describes the width of the arrow head.

- **length**
  A unit specifying the length of the arrow head (from tip to base).

- **ends**
  One of "last", "first", or "both", indicating which ends of the line to draw arrow heads.

- **type**
  One of "open" or "closed" indicating whether the arrow head should be a closed triangle.

**Examples**

```r
arrow()
```

**calcStringMetric**

*Calculate Metric Information for Text*

**Description**

This function returns the ascent, descent, and width metric information for a character or expression vector.

**Usage**

```r
calcStringMetric(text)
```

**Arguments**

- **text**
  A character or expression vector.

**Value**

A list with three numeric components named ascent, descent, and width. All values are in inches.
calcStringMetric

**WARNING**

The metric information from this function is based on the font settings that are in effect when this function is called. It will not necessarily correspond to the metric information of any text that is drawn on the page.

  test(tests[[i]])
  popViewport()
}

dataViewport Create a Viewport with Scales based on Data

Description
This is a convenience function for producing a viewport with x- and/or y-scales based on numeric values passed to the function.

Usage
dataViewport(xData = NULL, yData = NULL, xscale = NULL,
               yscale = NULL, extension = 0.05, ...)

Arguments

  xData A numeric vector of data.
  yData A numeric vector of data.
  xscale A numeric vector (length 2).
  yscale A numeric vector (length 2).
  extension A numeric. If length greater than 1, then first value is used to extend the xscale and second value is used to extend the yscale.
  ... All other arguments will be passed to a call to the viewport() function.

Details
If xscale is not specified then the values in x are used to generate an x-scale based on the range of x, extended by the proportion specified in extension. Similarly for the y-scale.

Value
A grid viewport object.
depth

Description

Determine the number of levels in a viewport stack or tree, in a viewport path, or in a grob path.

Usage

depth(x, ...)  
## S3 method for class 'viewport'
depth(x, ...)  
## S3 method for class 'path'
depth(x, ...)

Arguments

x          Typically a viewport or viewport stack or viewport tree or viewport list, or a
           viewport path, or a grob path.
...        Arguments used by other methods.

Details

Depths of paths are pretty straightforward because they contain no branchings. The depth of a
viewport stack is the sum of the depths of the components of the stack. The depth of a viewport tree
is the depth of the parent plus the depth of the children. The depth of a viewport list is the depth of
the last component of the list.

Value

An integer value.

See Also

viewport, vpPath, gPath.

Examples

vp <- viewport()
depth(vp)
depth(vpStack(vp, vp))
depth(vpList(vpStack(vp, vp), vp))
depth(vpPath("vp"))
depth(vpPath("vp1", "vp2"))
**deviceLoc**  

*Convert Viewport Location to Device Location*

**Description**

These functions take a pair of unit objects and convert them to a pair of device locations (or dimensions) in inches (or native device coordinates).

**Usage**

```r
deviceLoc(x, y, valueOnly = FALSE, device = FALSE)
deviceDim(w, h, valueOnly = FALSE, device = FALSE)
```

**Arguments**

- `x, y, w, h` A unit object.
- `valueOnly` A logical indicating. If `TRUE` then the function does not return a unit object, but rather only the converted numeric values.
- `device` A logical indicating whether the returned values should be in inches or native device units.

**Details**

These functions differ from the functions like `convertX()` because they convert from the coordinate systems within a viewport to inches on the device (i.e., from one viewport to another) and because they only deal with pairs of values (locations or dimensions).

The functions like `convertX()` convert between different units within the same viewport and convert along a single dimension.

**Value**

A list with two components, both of which are unit object in inches (unless `valueOnly` is `TRUE` in which case both components are numeric).

**Warning**

The conversion is only valid for the current device size. If the device is resized then at least some conversions will become invalid.

Furthermore, the returned value only makes sense with respect to the entire device (i.e., within the context of the root viewport).

- `unit`
Customising grid Drawing

### drawDetails

These generic hook functions are called whenever a grid grob is drawn. They provide an opportunity for customising the drawing of a new class derived from grob (or gTree).

#### Usage

```r
drawDetails(x, recording)
preDrawDetails(x)
postDrawDetails(x)
```

#### Arguments

- `x` A grid grob.
- `recording` A logical value indicating whether a grob is being added to the display list or redrawn from the display list.
**Details**

These functions are called by the grid.draw methods for grobs and gTrees.

preDrawDetails is called first during the drawing of a grob. This is where any additional viewports should be pushed (see, for example, grid:::preDrawDetails.frame). Note that the default behaviour for grobs is to push any viewports in the vp slot, and for gTrees is to also push and up any viewports in the childrenvp slot so there is typically nothing to do here.

drawDetails is called next and is where any additional calculations and graphical output should occur (see, for example, grid:::drawDetails.xaxis). Note that the default behaviour for gTrees is to draw all grobs in the children slot so there is typically nothing to do here.

postDrawDetails is called last and should reverse anything done in preDrawDetails (i.e., pop or up any viewports that were pushed; again, see, for example, grid:::postDrawDetails.frame). Note that the default behaviour for grobs is to pop any viewports that were pushed so there is typically nothing to do here.

Note that preDrawDetails and postDrawDetails are also called in the calculation of "grobwidth" and "grobheight" units.

**Value**

None of these functions are expected to return a value.

**Author(s)**

Paul Murrell

**See Also**

grid.draw

---

**editDetails**

*Customising grid Editing*

**Description**

This generic hook function is called whenever a grid grob is edited via grid.edit or editGrob. This provides an opportunity for customising the editing of a new class derived from grob (or gTree).

**Usage**

editDetails(x, specs)

**Arguments**

- `x` A grid grob.
- `specs` A list of named elements. The names indicate the grob slots to modify and the values are the new values for the slots.
editViewport

Details

This function is called by grid.edit and editGrob. A method should be written for classes derived from grob or gTree if a change in a slot has an effect on other slots in the grob or children of a gTree (e.g., see grid:::editDetails.xaxis).

Note that the slot already has the new value.

Value

The function MUST return the modified grob.

Author(s)

Paul Murrell

See Also

grid.edit

Description

This is a convenience function for producing a new viewport from a copy of an existing viewport (by default the current viewport), with specified modifications.

Usage

editViewport(vp=current.viewport(), ...)

Arguments

vp
A viewport object.

... Modification of the viewport (should all be valid arguments to the viewport() function.

Value

A grid viewport object.

Author(s)

Paul Murrell

See Also

viewport.
**explode**

*Explode a path into its components.*

**Description**
Explode a viewport path or grob path into its components.

**Usage**

```r
eplode(x)
# S3 method for class 'character'
eplode(x)
# S3 method for class 'path'
eplode(x)
```

**Arguments**

- `x`: Typically a viewport path or a grob path, but a character vector containing zero or more path separators may also be given.

**Value**
A character vector.

**See Also**
`vpPath`, `gPath`.

**Examples**

```r
eplode("vp1::vp2")
eplode(vpPath("vp1", "vp2"))
```

---

**gEdit**

*Create and Apply Edit Objects*

**Description**
The functions `gEdit` and `gEditList` create objects representing an edit operation (essentially a list of arguments to `editGrob`).

The functions `applyEdit` and `applyEdits` apply one or more edit operations to a graphical object. These functions are most useful for developers creating new graphical functions and objects.

**Usage**

```r
gEdit(...)
gEditList(...)
applyEdit(x, edit)
applyEdits(x, edits)
```
getNames

Arguments

... one or more arguments to the editGrob function (for gEdit) or one or more "gEdit" objects (for gEditList).
ox a grob (grid graphical object).
edit a "gEdit" object.
edits either a "gEdit" object or a "gEditList" object.

Value

gEdit returns an object of class "gEdit".
gEditList returns an object of class "gEditList".
applyEdit and applyEditList return the modified grob.

Author(s)

Paul Murrell

See Also

grob editGrob

Examples

grid.rect(gp=gpar(col="red"))
# same thing, but more verbose
grid.draw(applyEdit(rectGrob(), gEdit(gp=gpar(col="red"))))

getNames

List the names of grobs on the display list

Description

Returns a character vector containing the names of all top-level grobs on the display list.

Usage

getNames()

Value

A character vector.

Author(s)

Paul Murrell

Examples

grid.grill()
getNames()
Description

gpar() should be used to create a set of graphical parameter settings. It returns an object of class "gpar". This is basically a list of name-value pairs.
get.gpar() can be used to query the current graphical parameter settings.

Usage

gpar(...)  
get.gpar(names = NULL)

Arguments

...            Any number of named arguments.  
names         A character vector of valid graphical parameter names.

Details

All grid viewports and (predefined) graphical objects have a slot called gp, which contains a "gpar" object. When a viewport is pushed onto the viewport stack and when a graphical object is drawn, the settings in the "gpar" object are enforced. In this way, the graphical output is modified by the gp settings until the graphical object has finished drawing, or until the viewport is popped off the viewport stack, or until some other viewport or graphical object is pushed or begins drawing.

The default parameter settings are defined by the ROOT viewport, which takes its settings from the graphics device. These defaults may differ between devices (e.g., the default fill setting is different for a PNG device compared to a PDF device).

Valid parameter names are:

col    Colour for lines and borders.  
fill   Colour for filling rectangles, polygons, ...  
alpha  Alpha channel for transparency  
lty    Line type  
lwd    Line width  
lex    Multiplier applied to line width  
lineend Line end style (round, butt, square)  
linejoin Line join style (round, mitre, bevel)  
linemitre Line mitre limit (number greater than 1)  
fontsize The size of text (in points)  
cex    Multiplier applied to fontsize  
fontfamily The font family  
fontface The font face (bold, italic, ...)  
lineheight The height of a line as a multiple of the size of text  
font   Font face (alias for fontface; for backward compatibility)

For more details of many of these, see the help for the corresponding graphical parameter par in base graphics. (This may have a slightly different name, e.g. lend, ljoin, lmitre, family.)
Colours can be specified in one of the forms returned by `rgb`, as a name (see `colors`) or as a non-negative integer index into the current `palette` (with zero being taken as transparent). (Negative integer values are now an error.)

The `alpha` setting is combined with the alpha channel for individual colours by multiplying (with both alpha settings normalised to the range 0 to 1).

The `fill` setting can also be a linear gradient or a radial gradient or a pattern (see `patterns`).

The size of text is `fontsize*cex`. The size of a line is `fontsize*cex*lineheight`.

The `cex` setting is cumulative; if a viewport is pushed with a `cex` of 0.5 then another viewport is pushed with a `cex` of 0.5, the effective `cex` is 0.25.

The `alpha` and `cex` settings are also cumulative.

Changes to the `fontfamily` may be ignored by some devices, but is supported by PostScript, PDF, X11, Windows, and Quartz. The `fontfamily` may be used to specify one of the Hershey Font families (e.g., `HersheySerif`) and this specification will be honoured on all devices.

The specification of `fontface` can be an integer or a string. If an integer, then it follows the R base graphics standard: 1 = plain, 2 = bold, 3 = italic, 4 = bold italic. If a string, then valid values are: "plain", "bold", "italic", "oblique", and "bold.italic". For the special case of the HersheySerif font family, "cyrillic", "cyrillic.oblique", and "EUC" are also available.

All parameter values can be vectors of multiple values. (This will not always make sense – for example, viewports will only take notice of the first parameter value.)

`get.gpar()` returns all current graphical parameter settings.

**Value**

An object of class "gpar".

**Author(s)**

Paul Murrell

**See Also**

`Hershey`.

**Examples**

```r
gp <- get.gpar()
utils::str(gp)
## These *do* nothing but produce a "gpar" object:
gpar(col = "red")
gpar(col = "blue", lty = "solid", lwd = 3, fontsize = 16)
get.gpar(c("col", "lty"))
grid.newpage()
vp <- viewport(w = .8, h = .8, gp = gpar(col="blue"))
grid.draw(gTree(children=gList(rectGrob(gp = gpar(col="red")),
        textGrob(paste("The rect is its own colour (red)",
            "but this text is the colour",
            "set by the gTree (green)",
            sep = "\n")))))
  gp = gpar(col="green"), vp = vp))
grid.text("This text is the colour set by the viewport (blue)",
  y = 1, just = c("center", "bottom"),
  gp = gpar(fontsize=20), vp = vp)
```
gPath

grid.newpage()
## example with multiple values for a parameter
pushViewport(viewport())
grid.points(1:10/11, 1:10/11, gp = gpar(col=1:10))
popViewport()

---

**Description**

This function can be used to generate a grob path for use in `grid.edit` and friends.

A grob path is a list of nested grob names.

**Usage**

gPath(...)

**Arguments**

... Character values which are grob names.

**Details**

Grob names must only be unique amongst grobs which share the same parent in a gTree.

This function can be used to generate a specification for a grob that includes the grob’s parent’s name (and the name of its parent and so on).

For interactive use, it is possible to directly specify a path, but it is strongly recommended that this function is used otherwise in case the path separator is changed in future versions of grid.

**Value**

A `gPath` object.

**See Also**

grob, editGrob, addGrob, removeGrob, getGrob, setGrob

**Examples**

gPath("g1", "g2")
Grid Graphics

Description

General information about the grid graphics package.

Details

Grid graphics provides an alternative to the standard R graphics. The user is able to define arbitrary rectangular regions (called *viewports*) on the graphics device and define a number of coordinate systems for each region. Drawing can be specified to occur in any viewport using any of the available coordinate systems.

Grid graphics and standard R graphics do not mix!

Type `library(help = grid)` to see a list of (public) Grid graphics functions.

Author(s)

Paul Murrell

See Also

`viewport`, `grid.layout`, and `unit`.

Examples

```r
## Diagram of a simple layout
grid.show.layout(grid.layout(4,2,
        heights=unit(rep(1, 4),
        c("lines", "lines", "lines", "null")),
        widths=unit(c(1, 1), "inches")))
## Diagram of a sample viewport
grid.show.viewport(viewport(x=0.6, y=0.6,
        w=unit(1, "inches"), h=unit(1, "inches")))
## A flash plotting example
grid.multipanel(vp=viewport(0.5, 0.5, 0.8, 0.8))
```
Grid Viewports

Usage

viewport(x = unit(0.5, "npc"), y = unit(0.5, "npc"),
    width = unit(1, "npc"), height = unit(1, "npc"),
    default.units = "npc", just = "centre",
    gp = gpar(), clip = "inherit", mask = "inherit",
    xscale = c(0, 1), yscale = c(0, 1),
    angle = 0,
    layout = NULL,
    layout.pos.row = NULL, layout.pos.col = NULL,
    name = NULL)

vpList(...)
vpStack(...)
vpTree(parent, children)

Arguments

x
A numeric vector or unit object specifying x-location.
y
A numeric vector or unit object specifying y-location.
width
A numeric vector or unit object specifying width.
height
A numeric vector or unit object specifying height.
default.units
A string indicating the default units to use if x, y, width, or height are only given as numeric vectors.
just
A string or numeric vector specifying the justification of the viewport relative to its (x, y) location. If there are two values, the first value specifies horizontal justification and the second value specifies vertical justification. Possible string values are: "left", "right", "centre", "center", "bottom", and "top". For numeric values, 0 means left alignment and 1 means right alignment.
gp
An object of class "gpar", typically the output from a call to the function gpar. This is basically a list of graphical parameter settings.
clip
One of "on", "inherit", or "off", indicating whether to clip to the extent of this viewport, inherit the clipping region from the parent viewport, or turn clipping off altogether. For back-compatibility, a logical value of TRUE corresponds to "on" and FALSE corresponds to "inherit". May also be a grob (or a gTree) that describes a clipping path.
mask
One of "none" (or FALSE) or "inherit" (or TRUE) or a grob (or a gTree). This specifies that the viewport should have no mask, or it should inherit the mask of its parent, or it should have its own mask, as described by the grob.
xscale
A numeric vector of length two indicating the minimum and maximum on the x-scale. The limits may not be identical.
yscale
A numeric vector of length two indicating the minimum and maximum on the y-scale. The limits may not be identical.
angle
A numeric value indicating the angle of rotation of the viewport. Positive values indicate the amount of rotation, in degrees, anticlockwise from the positive x-axis.
layout
A Grid layout object which splits the viewport into subregions.
layout.pos.row
A numeric vector giving the rows occupied by this viewport in its parent’s layout.
Grid Viewports

layout.pos.col A numeric vector giving the columns occupied by this viewport in its parent’s layout.

name A character value to uniquely identify the viewport once it has been pushed onto the viewport tree.

parent Any number of grid viewport objects.

children A grid viewport object.
